## CERTIFICATE

This is to certify that the thesis entitled “**Novel Metal oxide Nanostructures for Adsorption and Photocatalytic degradation of Organic Dyes from Aqueous Stream**” being submitted by **Sri Jyoti Prakash Dhal** to the National Institute of Technology, Rourkela, India, for the award of the degree of **Doctor of Philosophy** is a record of bonafide research work carried out by him under my supervision and guidance. I am satisfied that the thesis has reached the standard for fulfilling the requirements of the regulations relating to the nature of the degree. To the best of my knowledge, the matter embodied in the thesis has not been submitted to any other University/Institute for the award of any Degree or Diploma.

Supervisor

**Place: Rourkela**  
**Date: 28-03-2016**

**Dr. Garudadhvaj Hota**  
**Department of Chemistry**

**Rourkela- 769008**

# Acknowledgement

I take this opportunity to express my deep sense of gratitude and indebtedness to my research supervisor **Prof. Garudadhvaj Hota**, for providing his excellent guidance, support, encouragement and inspiration throughout my research work. It has been a great opportunity to work with him with his vast scientific knowledge and analytical approach. I greatly feel fortunate enough for his patience to assist me, which he devoted from his busy schedule. Without his expertise and guidance, this work would not have been accomplished. I feel so lucky to have spent my research work under the guidance of an intelligent, forgiving, open minded, honest and beloved person like him. I am also very much thankful to his family members for their hospitality, love and encouragement.

I would also like to acknowledge **Prof. Braja Gopal Mishra**, my co-supervisor for providing his outstanding technical support, caring and valuable suggestions, which helped me making this research work a success.

I am extremely grateful to our honorable director sir **Prof. Sunil Kumar Sarangi**, a visionary personality, who encouraged and inspired through his motivating speech to carry out the research programme.

I am thankful to all my Doctoral Scrutiny Committee members **Prof. S. Paria**, **Prof. S. Mohapatra** and **Prof. S. Patel** for their valuable suggestions throughout my research career.

I would also like to express my deep sense of gratitude to **Prof. N. Panda**, HOD, Department of Chemistry, NIT Rourkela for allowing me to avail the experimental facilities.

I wish to express my sincere thanks to **Prof. R. K. Patel** (Ex-HOD), **Prof U. Subbudhi** and **Prof A. Mandal**, Department of Chemistry, NIT, Rourkela for good suggestions and useful discussions during my research work.

Above all, I am very much thankful and indebted to the **National Institute of Technology, Rourkela** for selecting me as a Ph. D. scholar and sponsored me financially throughout the research programme.

I would like to thank all the faculty and staff members, Department of Chemistry, NIT Rourkela for their help and inspirations.

I am very much grateful to Department of Physics, Ceramic and Metallurgical Engineering, NIT Rourkela, for providing various characterization techniques.

I wish to thank my lab mates Abhipsa, Shabna, Srabana, Bappaditya, Amar and Tapaswini for their immense help, timeless effort and cooperation throughout my work in laboratory. I would also like to thank all of my friends and seniors Rakesh bhai, Subrat bhai, Tapan, Ranjit, Achyut and Ranjit baba who supported me in writing, and incited me to strive towards my goal. My special thanks to Prakash, Smruti Snigdha, Subhraseema, Purabi, Uttam, Manoj, Kishore and Yagna for their companionship, emotional support and entertainment, which helped me a lot to get through the difficult times during my work.

Words cannot express how grateful I am to my mother (Bou) and father (Bapa) for all of their sacrifices that they have made on my behalf. I would like express appreciation to my grandmother, elder brothers (Bhai and Tikila Bhai), loving sister Lucky, younger brother Papa and Bhauja for their love inspiration, mental support and encouragement.

**August 2015**

**Jyoti Prakash Dhal**

## Abstract

Recent research focused on the applications of nanomaterials in environmental remediation especially the treatment of natural waters, industrial and domestic waste water and the polluted underground water. Providing clean water and a clean environment for the world growing population is a challenging task. The present thesis represents an extensive view of the use of nanomaterials in environmental remediation such as water purification using single and composite metal oxide nanomaterials by sorption and photocatalysis of toxic organic dyes.

In the present study, we have synthesized 1D iron oxide nanomaterials and iron oxide based nanocomposites such as  $\text{Fe}_2\text{O}_3\text{-SnO}_2$ ,  $\text{Fe}_2\text{O}_3\text{-CuO}$ ,  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$ , and  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3$  of different morphology using precipitation, hydrothermal and reflux methods. Apart from this we have also synthesized MgO nanomaterials and iron oxide impregnated mesoporous MCM-41 by wet chemical impregnation method. The obtained metal oxide nanomaterials and their nanocomposites were characterized using XRD, SEM, TEM, EDAX, XPS, Raman, FTIR, UV-Vis-DRS and BET surface area analytical techniques and were used as adsorbents and photocatalysts for decontamination of organic dyes from aqueous solutions.

We have synthesized ferrous oxalate, hematite and maghemite nanorods by precipitation method. The XRD patterns indicate the formation of different crystalline phases of ferrous oxalate ( $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ ), hematite ( $\alpha\text{-Fe}_2\text{O}_3$ ) and maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ). The SEM and TEM images confirm the formation of rod shaped morphology with diameter in the range of 100-200 nm and length up to micrometers. The prepared nanorods were used as adsorbents for removal of carcinogenic Congo red dye from aqueous solution. After the batch adsorption study, the maximum adsorption capacities of the adsorbents were found to be 103, 232 and 78 mg/g for  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ ,  $\gamma\text{-Fe}_2\text{O}_3$  and  $\alpha\text{-Fe}_2\text{O}_3$  nanorods, respectively. We have also prepared  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  composite nanorods by using same precipitation method. XRD study revealed the presence of magnetic  $\gamma\text{-Fe}_2\text{O}_3$  phase along with  $\text{SnO}_2$  in  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  composite. The  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  composite nanorods were used as adsorbents for removal of Congo red dye from aqueous solution. Among different compositions,  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe:Sn=8:2)

composite nanorod showed highest percentage adsorption with sorption capacity of 182 mg/g.

Mesoporous MCM-41 and MCM-41 impregnated with iron oxide nanomaterials (Fe-MCM-41) were prepared by a facile surfactant based wet chemical method. The experimental results indicate the formation of porous nanostructure with high surface area ( $>800 \text{ m}^2/\text{g}$ ) and particle size in the range of 200-400 nm. The mesoporous materials were used as adsorbents for the removal of Methylene blue from aqueous media. The maximum adsorption capacity of Fe-MCM-41 was found to be 194 mg/g and was higher than that of MCM-41.

MgO nanomaterials with different morphologies such as: nanorods, hierarchical nanostructures and nanoflakes were synthesized by precipitation, reflux and hydrothermal methods, respectively. The prepared nanomaterials were used as adsorbents to remove as Malachite green and Congo red from aqueous media. The hierarchical MgO nanostructure exhibited excellent adsorption performance for removal of Malachite green and Congo red with maximum sorption capacities of 1205 and 1051 mg/g, respectively. Using same synthesis methods we have used iron salt precursor along magnesium to prepare  $\text{MgFe}_2\text{O}_4$  and  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3$  composite nanostructures. The  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3$  nanocomposite prepared by precipitation method was regarded as a superb photocatalyst for 99.9 % methylene blue degradation.

We have also synthesized  $\text{Fe}_2\text{O}_3\text{-CuO}$  composite nanorod by same precipitation method. From FESEM and TEM analysis it was observed that the spherical CuO nanoparticles are decorated uniformly onto the  $\alpha\text{-Fe}_2\text{O}_3$  nanorod surface forming a one-dimensional heteronanostructure. The obtained 1D  $\text{Fe}_2\text{O}_3\text{-CuO}$  nanocomposite exhibited higher photocatalytic activity than individual  $\alpha\text{-Fe}_2\text{O}_3$  nanorods and CuO nanoparticles for degradation of Methyl orange from aqueous media under solar light irradiation.

Furthermore, we have synthesized  $\alpha\text{-Fe}_2\text{O}_3$  nanoparticle and  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4$ ,  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  and  $\text{ZnFe}_2\text{O}_4/\text{ZnO}$  mixed oxide nanocomposites by varying different molar ratio of Fe and Zn using hydrothermal method. The nanocomposite with Fe:Zn=70:30 and 60:40 contains ternary  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  phase. The nanomaterials have been used for photocatalytic degradation of Malachite green from aqueous media using solar light irradiation. The ternary  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30) nanocomposite exhibits highest photocatalytic activity among all the prepared nanomaterials. The enhanced activity could be

attributed to the cascade electron transfer from  $\text{ZnFe}_2\text{O}_4$  to  $\text{ZnO}$  to  $\text{Fe}_2\text{O}_3$  through the interfacial potential gradient in the ternary nanostructure.

# CHAPTER 1

## INTRODUCTION AND MOTIVATION

### 1. Background on Nanomaterials

Nano (like micro, pico, and so on) is a prefix used in front of a macroscopic unit to change its value by orders of magnitude. Nano means one billionth, or  $10^{-9}$ . Thus, one nanometer is one billionth of a meter (Balzani, 2005). Nanomaterials include the study of objects and systems with sizes in the range of 1-100 nm (Zhu et al., 2011). The nanosized materials are intermediate in size between atoms or small molecules and that of bulk structures. The dimensions of these systems are often equal to or smaller than the characteristic length scales that define the physical properties of materials. At these sizes, nanosystems can exhibit interesting and useful physical behaviors based on quantum phenomena (electron confinement, near-field optical effects, quantum entanglement, electron tunneling, and ballistic transport) or subdomain phenomena (superparamagnetism, overlapping double layers in fluids) (Love et al., 2005; Whitesides, 2005).

Nanocrystalline materials are the solids composed of nanometer sized particles, or grains, or crystallites (Valiev, 2002). Recent progress in nanomaterials research is regarded as one of the most advanced and interdisciplinary area of research in chemistry, physics, bioscience and engineering (Edelstein and Cammarata, 1998). The application of nanomaterials permits the alteration of the fundamental physical and chemical properties of conventional materials as their size is reduced to the nanoscale, offering new materials with unique electrical, optical and mechanical properties. Nanomaterials are being increasingly used for commercial purposes such as adsorbents, fillers, catalysts, semiconductors, photocatalysts, cosmetics, microelectronics, pharmaceuticals, drug carriers, energy storage and antifriction coatings (Farre et al., 2009; Yoshimatsu et al., 2008). The unique properties of nanomaterials, which arise due to the domination of surface effects over interior volume effect due to their nano dimension, can be used to design novel technologies or to improve the performance of existing processes. Nanomaterials have found multiple applications in water treatment, energy production, and contaminant sensing. In addition, a growing number of literatures also describe how novel nanomaterials can be used to address major environmental challenges (Perreault et al., 2015).

Water pollution is a major global problem threatening the life system which accounts for a large number of diseases and death by consuming contaminated water. There are various types of water contaminants such as inorganic pollutants like antimony, arsenic, barium, cadmium, chromium, fluoride, lead, mercury etc. and organic contaminants like acrylamide, phenol, benzene hexachloride, carbon tetrachloride and different organic dyes like congo red dye, methyl blue, methyl orange etc. (Chowdhury and Yanful, 2010; Bhounik et al., 2011; Yang and He, 2011; Cao et al., 2010). Dyes and pigments are widely using in paper, plastics, lathers, food and cosmetic industries as colour products. The toxic nature of dye is that on decomposition it gives hazardous products such as Carbon dioxide, carbon monoxide, nitrogen oxide and hydrogen chloride. These products are toxic and causes severe health problem to living beings (Iram et al., 2010; Kerkez and Bayazit, 2014). The various contaminants removal processes from wastewater sources include reverse osmosis, activated carbon filter, precipitation, membrane separation, ion exchange, adsorption, photocatalysis, solvent extraction, nanofiltration etc. Recent research focused on the use of nanotechnology for environmental clean-up/remediation. Arising out of their ultrafine size, large surface area & interface dominated properties nano-sized materials can be used to decontaminate the toxic organic and inorganic chemical from the environments.

In the past two decades, worldwide research efforts have been made both on theoretical and the experimental investigation of synthesis, growth, characterization and applications of inorganic nanostructures including metal oxides, ceramics and composites that have resulted in a mature, multidisciplinary field. Among the various classes of inorganic nanoparticles, metal oxide nanoparticles are particularly attractive from both the scientific and technological point of view. Metal oxide nanomaterials can exhibit unique physical and chemical properties due to their limited size and a high density of corner or edge surface sites (Fernández-García et al., 2004). Metal oxide nanomaterials have attracted a great deal of attention because of their large applications in various fields like catalysis, sensors and environmental remediation like adsorption and degradation of various contaminants from aqueous media (Oskam, 2006).

### **1.1. Nanorods/Nanofibers materials**

One dimensional (1D) nanomaterial, including nanotubes, nanowires, nanofibers and nanorods have attracted a great deal of attention due to their combination of superior properties like small dimension structure, high aspect ratio and unique device function that lead to a large range of promising applications in electronics, photonics, chemical sensors,

field emission devices, solar cells, lithium ion battery, hydrogen storage, and drug delivery (Zhao et al., 2011; Li et al., 2011; Mahapatra et al., 2011). One dimensional nanostructure possesses two quantum confined directions with one unconfined direction for electrical conduction; which allow these materials for electrical conduction rather than tunnelling transport. Besides that, the unique density of electronic states in the limit of small diameters is expected to exhibit significantly different optical, electrical and magnetic properties from their bulk 3D crystalline counterparts. Again, incorporation of functional heterostructures is a potential application of one-dimensional material which is very difficult or impossible in case of two-dimensional systems (Shankar and Raychaudhuri, 2005; Dick, 2008; Li et al., 2011; Zhanj and Zhu, 2002). Furthermore, one-dimensional nanostructures, such as nanowires, nanobelts, nanoribbons, nanorods and nanotubes, represent the smallest dimension for efficient transport of electrons and excitons and thus are ideal building blocks for hierarchical assembly of functional nanoscale electronic and photonic structures. Depending on the nature of materials, a nanowire obtained can have shown the properties of an insulator, a semiconductor or a conductor (Singh and Ali, 2010). Recently, well-defined 1-D nanostructures and/or 1-D arrays have been used for the establishment of many new and promising fields, including nanofabrication, nanodevices, nanobiology, nano-catalysis, etc. (Wang and Li, 2006).

In nanotechnology, one-dimensional (1-D) metal oxide nanostructures are the most important nanomaterials and current researchers are giving more focus towards these materials since they are the commonest minerals in the earth. They have gained great attention as a key component in ceramics, catalysis, sensors, transparent conductive films, electro-optical and electro-chromic devices. Intensive studies have been carried out on the synthesis of metal oxide nanowires as well as the exploration of their novel properties (Shen et al., 2009; Li et al., 2010; Comini et al., 2009). Over the past decade, one-dimensional (1D) semiconducting metal oxide nano-structures such as nanotubes (NTs), nanobelts (NBs), nanowires (NWs) and nanorods (NRs) have attracted extraordinary attention due largely to the unique physical and chemical properties associated with the 1D structural confinement at this scale (Zhou et al., 2010).

## **1.2. Mesoporous Materials**

Mesoporous materials are materials having pore sizes in the range of 2–50 nm. Due to combination of porous structure and high surface area these materials are expected to have

unique properties for applications in the field of adsorption, catalysis, membrane separation, fixing agent for biomolecule and semiconductor cluster, functional electronics and photonic applications (Nagata et al., 2006). MCM-41 (Mobil Composition of Matter) is the first ever synthesized mesoporous solid that showed a regularly ordered pore arrangement and a very narrow pore-size distribution (Ciesla and Schuth, 1999). It is a member of M41S family, contains of a hexagonal array of tubular pores possessing a high surface area i.e. more than  $1000 \text{ m}^2/\text{g}$  and uniform pore size distribution. MCM-41 material exhibits a regular, hexagonal arrangement of pores with one-dimensional parallel channels, formed a liquid crystal templating. It was synthesized with a self-assembly mechanism for the silicate source and surfactants with a long chain length as the template, and the structure of MCM-41 can be included with a metal atom to substitute  $\text{Si}^{4+}$  atom in the framework (Jehng et al., 2007). The presence of large internal surface area and favorable uniformity with easily controlled size of the pore enables the material (MCM-41) for applications of various fields in physics, chemistry, materials science, and other relevant areas such as: shape/size selective adsorbents, hosts for quantum structures, catalysts, and catalyst supports (Yu et al., 2001).

### **1.3. Nanocomposite materials**

A composite is considered to be any multiphase material that exhibits a significant proportion of the properties of all constituent phases such that a better combination of properties is realized. According to the principle of combined action, better property combinations are fashioned by the judicious combination of two or more distinct materials (Callister, 2007). Nanocomposites are composites in which at least one of the phases shows dimensions in the nanometre range ( $1 \text{ nm} = 10^{-9} \text{ m}$ ). Nanocomposite materials have emerged as suitable alternatives to overcome limitations of microcomposites and monolithics, while posing preparation challenges related to the control of elemental composition and stoichiometry in the nanocluster phase (Camargo et al., 2009). Nanocomposites are reported to be the materials of 21st century in the view of possessing design uniqueness and property combinations that are not found in conventional composites.

### **1.4. Importance of Metal oxide Nanomaterials**

Metal oxides nanomaterials are the common, most diverse, and important class of materials which attract research attention due to their unique physical, chemical, and structural properties. Metal elements are able to form different types of oxide compounds, which can adopt a vast number of structural geometries with an electronic structure with metallic,

semiconductor or insulator character. They include optical, optoelectronic, magnetic, electrical, thermal, electrochemical, photoelectrochemical, mechanical, and catalytic properties (Vayssieres, 2004). The efficiency of the aforesaid properties of metal oxides largely varies with the reduction of particle size into nano scale and which is either enhanced or completely novel properties compared to their bulk materials (Zhang, 2008).

#### 1.4.1. Iron Oxides

Iron oxide nanoparticles have been attracting much attention of researchers for its environmental benignity, multivalent oxidation states, abundant polymorphism, mutual polymorphous changes in nanophase, nontoxicity and low cost (Zhu et al., 2014). Iron oxides exist in different phases in nature including oxides, hydroxides and oxy-hydroxides. Some of them are: FeO, Fe<sub>3</sub>O<sub>4</sub>, Fe<sub>4</sub>O<sub>5</sub>, Fe<sub>4</sub>O<sub>3</sub>, polymorphs of Fe<sub>2</sub>O<sub>3</sub> ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, and  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>), Fe(OH)<sub>3</sub>, FeOOH and so on. Among different phases of iron oxide, the magnetite (Fe<sub>3</sub>O<sub>4</sub>), the maghemite ( $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>), and the hematite ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>) are probably the most common for fundamental study and also very important in technologically and hence therefore, the subject of discussion. Hematite ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>) is the most stable iron oxide under the ambient conditions and has a great scientific and technological importance because of its n-type semiconducting properties due to its narrow band gap of 2.2 eV, chemical and thermal stability and nontoxicity. This compound possesses rhombohedral, corundum ( $\alpha$ -Al<sub>2</sub>O<sub>3</sub>) structure which is the most common form. It shows antiferromagnetic behaviour below ~260 K (Morin transition temperature), and exhibits weak ferromagnetism between 260 K and 950 K (Neel temperature). Apart from this, Hematite ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>) is a potential photocatalyst which can be driven by visible light up to 600 nm (Zhang et al., 2012; Chen et al., 2006). But, Magnetite (Fe<sub>3</sub>O<sub>4</sub>) assumes inverse cubic spinel structure in which iron cation exists in two oxidation states of Fe<sup>2+</sup> and Fe<sup>3+</sup> and hence shows very interesting properties. Magnetic properties of magnetite nanoparticles have been widely studied because of their relevance to magnetic recording, biomedical applications and so on (Daou et al., 2006). Maghemite ( $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>) is a ferrimagnetic spinel in which the magnetic Fe<sup>3+</sup> ions with spin S=5/2 are disposed in two sublattices with different coordination with the O<sup>2-</sup> ions. At ambient conditions, these phases are thermodynamically less stable than hematite. Maghemite is used in large number of applications i.e. magnetic resonance imaging, magnetic recording media, fabrication of biocompatible magnetic fluids and electronic devices. Nanoparticles of maghemite ( $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>) have many advantages as an adsorbent, such as high adsorptive capacity, easy and fast

production, rapid uptake, and easy separation of the metal loaded magnetic adsorbent from treated water via an external magnetic field (Akhbarizadeh et al., 2014).

#### **1.4.2. Iron oxide based composite nanomaterials**

Metal oxide composite nanomaterials have been emerging as alternative adsorbents for the scavenging of toxic organic dyes from wastewater. The hybrid nanostructured materials show unusual mechanical, thermal, physical, and chemical properties. They also have a large surface area, which makes the composite materials quite promising as good adsorbents and photocatalysts (Ahmad and Kumar, 2010). Iron oxide based nanocomposite materials have been found to exhibit interesting physicochemical properties suitable for many advanced technological applications such as catalysts, adsorbents for removal of toxic ions and organic dyes, sensors, magnetic-optical materials, and many more applications. The coupling or incorporation of some other metal ion into the lattice structure of  $\text{Fe}_2\text{O}_3$  form iron oxide based mixed oxide nanocomposites. They are very good materials for the sorption and photocatalytic studies, because combination of other metal oxides with  $\text{Fe}_2\text{O}_3$  lattice structure enhanced the material properties namely surface sorption, photo-induced catalysis, etc. The improved physicochemical properties of these complex oxides is due to incorporation of additive metal oxides which changes the surface characteristics and micro-structure (Gupta and Ghosh, 2009; Wu et al., 2012). Compare to single iron oxide, iron oxide based nanocomposites offer a potential material as a result of the synergic effect that is possible among the components. Although iron oxide ( $\text{Fe}_2\text{O}_3$ ) is a low cost, non toxic, high chemical stability and visible-light-driven photocatalyst, the single component semiconductor ( $\alpha\text{-Fe}_2\text{O}_3$ ) has a number of disadvantageous features including low light harvesting, high recombination rate of electron-hole pairs, and hardly being able to be separated and recycled. Therefore, in recent years, more attention have been paid to combine a variety of different semiconductor metal oxides components and ion doping or introduce noble metals in order to precisely control nanostructures and the corresponding properties (Sun et al., 2014). Iron oxide ( $\text{Fe}_2\text{O}_3$ )-based nanocomposites have been proved to be effective adsorbent materials and photocatalysts with improved sorption properties as well separation efficiency of photogenerated electron-hole pairs.

#### **1.5. Synthetic Techniques of Metal Oxide Nanomaterials**

Several synthetic approaches have been developed for synthesizing metal oxide nanomaterials over the past few decades. But the synthesis of nanomaterials with controlled

size, shape and morphology has long been of scientific and technological interest. Up to now, many techniques have been developed in the synthesis of metal oxide nanomaterials. Basically, they can be described as two different types: the “top-down” approaches and the “bottom-up” approaches. Top-down methods use bulk materials of desired composition, and achieve nanoscale dimensions by lithographic techniques (UV, electron or ion beam, scanning probe, optical near field), laser-beam processing, and mechanical techniques (machining, grinding, and polishing) that essentially carve the desired structure out of the material. However, there are many practical problems in the methods such as: techniques to carve out ever-smaller structures are difficult to find. More importantly, uniformity of bulk crystals on nanometer length scales is not very high, and quality of structures becomes difficult to control (Dick, 2008). “Bottom-up” approaches, on the other hand, exploit the chemical properties of the molecules to cause self-assembling atoms to form increasingly larger structures. Such techniques involve controlled crystallization of materials from vapour or liquid sources, typically yielding uniform and highly ordered nanometer scale structures. The most common bottom-up approaches are chemical synthesis, chemical vapor deposition, laser-induced assembly, self-assembly, colloidal aggregation, film deposition and growth. The bottom-up approach can produce much smaller sized particles and has the potential to be more cost-effective in the future because of the advantages of absolute precision, control over the process, and minimum energy loss compared with that of a top-down approach (Chaudhuri and Paria, 2012). Significant progress has been made over the last decade in understanding fundamental aspects of the synthesis of nanoparticles, nanorods, nanofibers, nanowires, nanotubes, nanoflakes and hierarchical nanostructures. Metal oxides can be prepared using a number of synthetic techniques, which are broadly classified into two categories, namely, physical methods and chemical methods.

#### **1.5.1. Physical Methods**

The methods of generation of nanomaterials in the gas or solid phase using high-energy treatment of the material are usually called physical methods. The various physical methods include laser ablation, sputtering, high energy ball milling, vapor deposition, electro-deposition and so on. In our research work we have used chemical methods for synthesis of metal oxide nanomaterials.

#### **1.5.2. Chemical Methods**

Chemical synthesis methods are the most promising strategy to exploit science and technology at the nanometer scale, in which the building of materials occur from the bottom

i.e. atom by atom, molecule by molecule or cluster by cluster. Various synthesis methods can be grouped into two categories: thermodynamic approach or kinetic approach. In the thermodynamic approach, synthesis process consists of (i) generation of super saturation, (ii) nucleation, and (iii) subsequent growth. In kinetic approach, formation of nanoparticles is achieved by either limiting the amount of precursors available for the growth or confining the process in a limited space. Chemical methods have been playing a major role in developing nanomaterials with desired shapes, morphologies and sizes such as: nanorods, nanofibers, nanowires, nanotubes, nanoplates, nanoflakes, spherical, cubical, elliptical nanoparticles, and nanocomposites with novel and technological important properties. In our study we have followed three chemical methods namely chemical precipitation, reflux and hydrothermal methods for preparation of iron oxide and iron based composite nanomaterials. Brief description of precipitation, reflux and hydrothermal methods for metal oxide nanomaterial synthesis are as follows:

### **Hydrothermal Method**

Hydrothermal method is a chemical method where heterogeneous reaction takes place in the presence of aqueous solvents or mineralizers under high pressure and temperature conditions. This is a process that utilizes single or heterogeneous phase reactions in aqueous media at elevated temperature ( $T > 25\text{ }^{\circ}\text{C}$ ) and pressure ( $P > 100\text{ kPa}$ ) to crystallize metal oxide materials directly from solution. Since ionic product of water ( $K_w$ ) has a maximum value of around  $250\text{--}300\text{ }^{\circ}\text{C}$ , hydrothermal synthesis is usually carried out below  $300\text{ }^{\circ}\text{C}$ . The crystal growth is performed in an apparatus consisting of a steel pressure vessel called autoclave, which is hermetically sealed in order to withstand high temperatures and pressures for prolonged periods of time. The contribution of the dielectric constant to the reaction rates becomes remarkable based on the electrostatic theory. The main advantages of hydrothermal synthesis over conventional and non-conventional methods is that all forms of metal oxides can be prepared with hydrothermal synthesis, namely powders, fibers, rods, wires, tubes, cubes, spheres, flakes, ellipses and single crystals, monolithic ceramic bodies, and coatings on metals, polymers, and ceramics (Byrappa and Adschiri, 2007; Wojciech et al., 2006). In addition, powders prepared by hydrothermal route are known to produce pure and crystalline oxide powders with relatively narrow size distribution (Panda et al., 2006). For synthesis of metal oxide nanomaterials, first hydrated metal ions are hydrolyzed to metal hydroxide. Then, metal hydroxides proceed to precipitate as metal oxides through dehydration. Hydrolysis is regarded as an electrostatic reaction between metal ions and hydroxyl ions.

Hematite ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>) nanotubes have been prepared by hydrothermal method and their catalytic performance for thermal decomposition of ammonium perchlorate was studied (Song et al., 2010). Similarly, SnO<sub>2</sub>/graphene (GN) composite was fabricated via a simple one-pot hydrothermal method with graphene oxide (GO) and SnCl<sub>2</sub> as the precursors (Lin et al., 2012).

Solvothermal synthesis is a method of producing nanomaterials, which is very similar to the hydrothermal route, the only difference being that the precursor solution is usually different organic solvents rather than aqueous. Zhou et al. (2015) have synthesized ZnO/ $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> composites in which plenty of ZnO nanoparticles decorated on the surfaces of uniform round-edged  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> hexahedrons via a facile solvothermal method using ethylene glycol solvent.

### **Precipitation Method**

Precipitation method is a facile way of synthesis of metal oxide nanomaterials, which attracts considerable interest in industries because of low energy and temperature, inexpensive and cost-effective approach for large scale production and good yield. In this method, precipitation of solids from a solution with metal ions occurs by pH adjustment. In supersaturated solutions, particles are formed via homogeneous or heterogeneous nucleation. The growth of particles usually occurs via diffusion or Ostwald ripening concentration and temperature has a big influence on the growth rate. Particle size and particle size distribution, crystallinity as well as morphology of the nanomaterials are controlled by applying reaction kinetics. The important parameters involve in precipitation method are the concentration, the temperature, the pH of the solution, the order of adding the reactants and mixing processes (Rao and Müller, 2005). Hexagonal zinc oxide (ZnO) nanoparticles have been synthesized by precipitation method using zinc nitrate as a precursor and NaOH starch as a stabilizing agent (Lanje et al., 2013). Co-precipitation method is similar to this method, where two or more precipitants are have been used and usually reaction proceeded at temperature below 100 °C. Pure maghemite ( $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>) nanoparticles were prepared via co-precipitation method using urea and ammonia as precipitation agent for ferrous and ferric ions at ambient temperature (Wu and Gao, 2013). Superparamagnetic ferrite nanoparticles (MFe<sub>2</sub>O<sub>4</sub>, where M = Fe, Co, Mn) were synthesized through one-step aqueous co-precipitation method by using alkaline agent, alkanolamines isopropanolamine and diisopropanolamine (Pereira et al., 2012).

## **Reflux Method**

Reflux synthesis methods in wet chemistry include techniques that normally involve relatively lower reaction temperatures compared with hydrothermal synthesis, a very positive aspect in the fabrication of metal oxide nanomaterials. The reflux condensation method can be used when the solvent has boiling point lower (example 50-60 °C) to avoid any loss amount and at same time the temperature of refluxing depends on the dissolve of starting materiel that can produce the final nano-particle. The reflux condensation technique can be used in sol gel or precipitation or any methods. CuO with urchin-like morphologies has been synthesized via a simple reflux method using  $\text{Cu}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$  and urea precursors dissolved in the solvent of distilled deionized water and ethylene glycol monomethyl ether in a round-bottom flask kept in an oil bath at 100 °C for 6 h (Xu et al., 2009).

## **1.6. Applications of Metal Oxide Nanomaterials**

Metal oxide nanomaterials can exhibit unique physical and chemical properties due to their limited size and a high density of corner or edge surface sites. They have attracted a great deal of attention recent research because of their applications in various fields like catalysis, sensors, optical, electronic, magnetic, biological and environmental remediation like photocatalytic degradation and adsorption of various contaminants from water. In this research work we have focoused on environmental applications of metal oxide nanomaterials specifically adsorptive removal and photocatalytic degradation of organic dyes from aqueous media.

### **1.6.1. Environmental Applications**

Due to worldwide population growth, rapid development of industrialization and use of pesticides, insecticides etc. in agriculture fields, a wide range of organic and inorganic pollutants contaminant the surface and ground water which deteriorates the environment and affects the living organism. Thus, the prevention of the harmful effects of contaminants is necessary to keep the environment safe and improve the human living conditions. The various contaminants persisting in wastewater include heavy metals, inorganic compounds, organic dyes, chlorinated hydrocarbons and many other complex compounds. Organic dyes imparts colour to substances such as textile fibers, leather, plastic materials, papers, or wax either in solution or dispersion. Among industrial wastewater, organic dyes distrached from the textile, lether, plastics and paper industries are major source of organic pollutants. They are very hazardous to living beings and ecological environments. Dye molecules include of

two key components: the chromophores, responsible for producing the colour, and the auxochromes, which can not only supplement the chromophore but also render the molecule soluble in water and give enhanced affinity toward the fibers. This is because organic dyes usually have a synthetic origin and complex aromatic structures which make them stable and more difficult to be biodegrade (Gupta and Suhas, 2009). These organic dye contaminants are releasing into the environment through wastewater. Even just 1.0 mg/L of dye concentration in drinking water could impart a significant color, making it unhealthy for human consumption. Furthermore organic dyes can affect aquatic plants because they reduce sunlight penetration into water there by decreasing the efficiency of photosynthesis and hence having adverse effect on their growth. Also dyes molecules may impart toxicity to aquatic life and may be mutagenic, carcinogenic and may cause severe damage to human beings, such as dysfunction of the kidneys, reproductive system, liver, brain and central nervous system. Generally, the organic dyes used in the textile industries are basic dyes, acid dyes, reactive dyes, azo dyes, disperse dyes and sulfur dyes. The organic dyes can be classified as cationic, anionic and nonionic dyes. Cationic dyes are basic dyes while the anionic dyes include acid and reactive dyes (Salleh et al., 2011). Nowadays, there is an increasing concern over worldwide for the development of dye wastewater treatment technologies (Xu et al., 2012). The different processes of removing the dye contaminants present in water to clean the environment by using nanotechnologies are nanofiltration, bioremediation, adsorption by nanomaterials, photocatalysis by semiconductor metal oxide nanomaterials and so on. Keeping the hazardous nature and harmful environmental effects in view, we have made systematic efforts for complete removal of different organic dyes pollutants from wastewaters by using novel iron oxide based other metal oxide composite nanomaterials adsorbents and photocatalysts.

### **Adsorption**

Adsorption is commonly employed as a polishing step to remove organic and inorganic contaminants in water and wastewater treatment. Efficiency of conventional adsorbents is usually limited by the surface area or active sites, the lack of selectivity, and the adsorption kinetics. Nowadays, nanoadsorbents have been appeared as an alternate source for conventional adsorbents. Metal oxide nanoadsorbents are widely studied due to their unique properties compared to their bulk counterpart (Nassar, 2012). Arising out of their ultrafine size, large surface area, associated sorption sites, short intra-particle diffusion, high density of corner or edge surface sites, tunable pore size, chemical stability and nontoxicity, metal oxide

nano-adsorbents offer significant improvement in the field of adsorption (Qu et al., 2013). Chaudhary et al. (2013) have synthesized  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles with controlled morphology using chemical precipitation method and studied adsorptive removal of hazardous azo dye such as Congo red by using the  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles. They reported that 98 % of the dye was effectively removed from water. Hematite ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>) nanofibers synthesized by hydrothermal method was found to be a potential adsorbent for removal and recovery of noxious Cr(VI) from wastewater (Ren et al., 2013). Mesoporous  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>/SiO<sub>2</sub> nanocomposite prepared by sol-gel method was found to be a superb adsorbent for removal of methyl orange dye from aqueous media with maximum adsorption capacity of 476 mg/g (Deligeer et al., 2011).

### **Photocatalysis**

Photocatalytic oxidation is an advanced oxidation process for degradation of organic dyes and other toxic organic compounds. It is a useful pretreatment for hazardous and non-biodegradable contaminants to enhance their biodegradability. In photogenerated catalysis, the photocatalytic activity (PCA) depends on the ability of the catalyst to create the electron–hole pairs, which generate free radicals (e.g. hydroxyl radicals:  $\cdot$ OH) which are able to undergo secondary reactions. In recent years, degradation of organic pollutants in waste water is one of the most active areas in heterogeneous photocatalysis. In a heterogeneous photocatalysis system, photoinduced molecular transformations or reactions take place at the surface of a catalyst. Recently, Madrakian et al. (2014) have synthesized  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>/TiO<sub>2</sub> nanocomposite by wet chemical method and found that the nanocomposite can efficiently degrade Janus Green B, a cationic dye, and Congo red, an anionic dye under solar light irradiation with better performance than bare TiO<sub>2</sub> nanoparticles. Ahmed et al. (2015) have synthesized nanocrystalline ZnO,  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and ZnFe<sub>2</sub>O<sub>4</sub>/ZnO by solution combustion method and studied the photocatalytic degradation of Brilliant yellow dye from aqueous solution using the nanomaterials. They reported that ZnFe<sub>2</sub>O<sub>4</sub>/ZnO showed better photocatalytic activity for the degradation of Brilliant yellow dye than ZnO and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>.

## **1.7. Organization of the thesis**

The present thesis is organized into seven chapters. The present chapter (Chapter-1) represents the introduction to nanomaterials, one dimensional nanomaterial, composite nanomaterials, metal oxide nanomaterials, their synthesis and applications. Chapter-2 contains an extensive literature review on metal oxide nanomaterials synthesis by wet

chemical methods and their environmental application towards adsorption and photocatalysis of organic dyes from aqueous media. Chapter-3 contains two parts. Both the first and second parts describes the synthesis of  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ ,  $\gamma\text{-Fe}_2\text{O}_3$  and  $\alpha\text{-Fe}_2\text{O}_3$  nanorods and  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  composite nanorods by precipitation method and their application towards adsorption of Congo red dye from aqueous media. Chapter-4 describes synthesis of mesoporous MCM-41 and iron oxide dispersed mesoporous MCM-41 and their application towards adsorptive removal of Methylene blue dye from aqueous solution. Chapter-5 contains two parts. The first part represents the synthesis and high adsorption properties of MgO nanomaterials with three different morphology for removal of malachite green and Congo red dyes. The second part describes the synthesis of magnesium ferrite nanocomposites by three different wet chemical methods for photocatalytic degradation of Methylene blue dye form aqueous solution under solar light irradiation. In Chapter-6, the synthesis of one dimensional  $\text{Fe}_2\text{O}_3\text{-CuO}$  nanocomposites and their photocatalytic activity towards degradation of Methyl orange dye have been discussed. Chapter-7 is about the synthesis of ternary  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  nanocomposites and their enhanced photocatalytical activity for degradation of Malachite green dye under solar light irradiation. Finally, Chapter-8 concludes our research works and highlights our contribution.

# CHAPTER 2

## REVIEW OF BACKGROUND LITERATURE

In this chapter, we have reported a review of the current developments in the area of synthesis and characterization of iron oxide and iron oxide based nanocomposites, ferrites, and mesoporous MCM-41 nanomaterials using different chemical methods such as: precipitation, hydrothermal and reflux methods. Apart from this the basic principles of formation along with the advantages and disadvantages using these synthetic techniques have been briefly presented. Again, the environmental applications of these metal oxide nanomaterials such as: adsorption and photocatalytic degradation of organic dyes have also been discussed.

### 2.1. Precipitation Method

Precipitation method is a simple and well established wet chemical processes in which solutions of the different ions are mixed under controlled temperature, concentration and pH to form insoluble precipitates. Precipitation approach in comparison to with other traditional methods provides a facile way for low cost and large-scale production, which does not need expensive raw materials and complicated equipments. In this method, particle growth takes place by interaction between different ions present in the solutions and therefore very small particles are formed via diffusion or Ostwald ripening concentration and temperature. Tiny size particles with lower solubility product dissolve and re-precipitate on the surface of larger particles in solution; consequently agglomeration takes place in solution as the particles clog together to minimize surface energy (Bagheri et al., 2013). In this method the particles size, size-distribution, crystallinity as well as morphology of the prepared nanomaterials are controlled by applying reaction kinetics.

**Advantages:** The precipitation method is the simplest, most efficient, environment friendly and rapid preparative chemical pathway to obtain metal oxide nanomaterials. The main advantage of the precipitation method is that a large scale production of nanomaterials can be achieved within a short time interval. Easy control of composition with better homogeneity can be made in this method and also, there are various possibilities to modify the particle surface. Moreover the precipitation reaction can be carried out mostly in aqueous or greener solvent media, which are environment friendly (Nazari et al., 2014; Mohapatra and Anand, 2010; Kumar et al., 2013; Vivekanandhan, 2010).

**Disadvantages:** The control of particle size distribution is limited, because only kinetic factors are controlling the growth of the crystal. Universal experimental condition for the synthesis of various types of metal oxides is not possible by this method. It is not a suitable method for the reactants having different solubility as well as different precipitate rate (Mohapatra and Anand, 2010; Vivekanandhan, 2010).

### 2.1.1. Metal oxide nanomaterials by precipitation method

Nanorods as one-dimensional nanomaterials have attracted much attention due to their peculiar properties, which is due to their high surface area and low dimensionality. One-dimensional (1-D) metal oxide nanostructures are the most important nanostructures and recent research on the synthesis and application of 1D nanomaterial in various fields. They have gained great attention as a key component in ceramics, catalysis, sensors, transparent conductive films, electro-optical and electro-chromic devices. Intensive studies have been carried out on the synthesis of metal oxide nanowires as well as the exploration of their novel properties (Shen et al., 2009; Li et al., 2010; Comini et al., 2009). Yao et al. (2011) have prepared porous hematite ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>) nanorods, having diameters of 30-60 nm (figure 2.1), through thermal decomposition of FeC<sub>2</sub>O<sub>4</sub>·2H<sub>2</sub>O nanorods which were readily synthesized through poly(vinyl alcohol)-assisted precipitation process. They have reported that the formation of porous structure of the nanorod due to the release of CO<sub>2</sub> during the decomposition of FeC<sub>2</sub>O<sub>4</sub>·2H<sub>2</sub>O. Compared to the commercial  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> submicrometer powders, the porous  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods are revealed as a superior electrode material in lithium-ion batteries, due to their nanorod shape and porous structure.

**Figure 2.1** (a, b) SEM images of FeC<sub>2</sub>O<sub>4</sub>·2H<sub>2</sub>O nanorods; (c, d) SEM images of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods, (e) TEM image of a individual  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorod, the inset is the corresponding SAED pattern, (f) HRTEM image of the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorod (Yao et al., 2011).

Qiaoling et al. (2009) have synthesized one dimensional (1D) hematite ( $\alpha\text{-Fe}_2\text{O}_3$ ) nanorods with average diameter 60 nm and length up to 800 nm by simple chemical precipitation method. During preparation of  $\alpha\text{-Fe}_2\text{O}_3$ , the length of  $\alpha\text{-Fe}_2\text{O}_3$  was found to be increased by the addition of polyethylene glycol (PEG) and the diameter was found to be decreased by addition of  $\text{Zn}^{2+}$ . MgO nano-rods of several microns in length and 50-100 nm in width were prepared by Sutradhar et al. (2011) by calcining nesquehonite phase, which was obtained by simple precipitation using  $(\text{NH}_4)_2\text{CO}_3$  under ambient condition. The preparation method was flexible and easily scalable which avoids extreme reaction conditions, high pressure treatment and longer processing time. It was based on controlled growth of nesquehonite phase in unique rod morphology using cheap and abundant chemicals. The synthesized MgO nano-rod exhibited strong activity in solvent-free base catalyzed Claisen-Schmidt condensation giving 99 % conversion in 2 h and was easily recyclable with no significant change in catalytic activity. Sangari and Devi (2013) have synthesized ZnO nano rods by reacting zinc nitrate and potassium hydroxide via microwave assisted chemical precipitation method. The amount of potassium hydroxide was adjusted for three different pHs to achieve ZnO nano rods with varying aspect ratio. From figure 2.2, it is observed that at pH 9 and 11, ZnO powder exhibited well separated rods with few tetrapod and flower-like structures with each petal having the single hexagonal rod shape respectively.

**Figure 2.2** SEM images of synthesized ZnO rods obtained at (a) pH 9 and (b) pH 11 (Sangari and Devi, 2013).

Very fine, single crystalline hexagonal nano crystals of  $\gamma\text{-Fe}_2\text{O}_3$  (maghemite) with particle size of ~70-100 nm were synthesized by emulsion precipitation method using kerosene as oil phase, SPAN-80 (sorbitane monooleate) as the surfactant and sodium hydroxide as the precipitating agent. When the  $\gamma\text{-Fe}_2\text{O}_3$  was calcined in the temperature range of 500 to 850  $^{\circ}\text{C}$ , the  $\gamma\text{-Fe}_2\text{O}_3$  was transferred to  $\alpha\text{-Fe}_2\text{O}_3$  (hematite) nanoparticles (Sahoo et al., 2010). Sarangi et al. (2009) have synthesized single-phase  $\alpha\text{-Fe}_2\text{O}_3$  nano-powders with particle

size~20–30 nm using two simple chemical precipitation methods. In method 1, an aqueous solution of ferric nitrate was mixed with aqueous solution of PVA by vigorously stirring. Then, a dark brown colored fluffy precursor was formed when this mixture was dried and calcined in air for 2.30 h at 250 to 450 °C to form  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles. In method 2, they have followed the first method by using EDTA solution instead of PVP solution. BET surface area of calcined powders, prepared from method-1 and method-2, was found to be 35 and 20 m<sup>2</sup>/gm, respectively. In 2013 Naje et al. have synthesized nanocrystalline tetragonal rutile SnO<sub>2</sub> with crystalline size in the range of 8-10 nm by a chemical precipitation method. In a typical synthesis procedure, they added ammonia solution to stannous chloride dehydrate (SnCl<sub>2</sub>·2H<sub>2</sub>O) solution drop wise under stirring to form gels, which was dried and calcined at 550 °C for 2h to form SnO<sub>2</sub> nanopowder. Bakhtiari et al. (2011) have synthesized CuO nanoparticles by the direct thermal-decomposition of brochantite (Cu<sub>4</sub>(SO<sub>4</sub>)(OH)<sub>6</sub>) at 750 °C for 2 h. The brochantite was synthesized by precipitation method in which Na<sub>2</sub>CO<sub>3</sub> solution was added drop wise to copper (II) sulfate solution with vigorous stirring to form green precipitate. The green precipitate was then filtered and dried at 70 °C for several hours to form brochantite. Similarly, semiconductor CuO nanoparticles were synthesis by a simple precipitate method using copper acetate and glacial acetic acid precursor. In a typical procedure, copper acetate aqueous solution was mixed with glacial acetic acid and aqueous NaOH solution was added to the mixture at different temperatures until the pH value of the mixture reached to 6.5. A large amount of the black CuO precipitate was produced which was stirred for 30 min at different temperatures (10, 20, 60 and 115 °C) to form CuO nanoparticles. It is observed that in the absence of ultrasonic irradiation needle-like CuO nanostructures with an average diameter of 16–27 nm were formed and under ultrasonic condition uniform CuO spherical nanoparticles with particle size distribution in the range of 12–15 nm were obtained. The band gap of samples was estimated to be in the range of 1.9–2.9 eV that is larger than the reported value for the bulk CuO (1.85 eV). Wang and co-workers (2007) have synthesized MgO nanoplates via chemical precipitation using ammonia hydroxide as precipitator in the presence of a nonionic surfactant polyethylene glycol (PEG 400). It is observed that the particles have a plate-like shape with thickness is in the range of 10–20 nm and length is up to 100 nm when less amount of ammonium hydroxide is used and the MgO particles aggregate into large flocks, which could be attributed to the relative deficiency of PEG 400 to cap the precursor with the increase of the nuclei, when high of NH<sub>3</sub>·H<sub>2</sub>O is used. In 2012, Veldurthi et al. have synthesized single crystals of mesoporous plate-like MgO nanoparticles using a simple precipitation method without using any

templates. Initially,  $\text{Mg(OH)}_2$  was synthesized by the precipitation of magnesium nitrate solution and then the  $\text{Mg(OH)}_2$  was calcined to form plate-like  $\text{MgO}$  nanocrystals. Yadav et al. (2008) have synthesized  $\text{ZnO}$  nanomaterial through pyrolysis of the oxalate, which was produced by a conventional precipitation method. In the method, a sodium oxalate solution was mixed with a zinc sulphate solution at room temperature in the molar ratio 1:1 to yield a precipitate of zinc oxalate. This precipitate was filtered out and washed, dried and calcined at  $450^\circ\text{C}$  for 15 min to form zinc oxide nanopowder. The prepared  $\text{ZnO}$  nanoparticles have good sensing properties for water vapour. Chen and co-workers (2008) have synthesized  $\text{ZnO}$  nanoparticles by direct precipitation method via the reaction between Zinc nitrate ( $\text{Zn(NO}_3)_2$ ) and ammonium carbonate ( $(\text{NH}_4)_2\text{CO}_3$ ) in aqueous solutions. The SEM morphology (figure 2.3) of the nano-sized  $\text{ZnO}$  particles suggested that the particles are pseudo-spherical in shape. Moharram et al. (2014) have synthesized  $\text{ZnO}$  nanoparticles with crystalline size about  $22.4 \pm 0.6$  nm through hydrolysis and condensation of zinc acetate dihydrate by potassium hydroxide in alcoholic medium at low temperatures. Similarly, Gao et al. (2013) have synthesized hierarchically structured  $\text{ZnO}$  nanocrystallite aggregates through an interface precipitation method by taking zinc acetate dihydrate and  $\text{NaOH}$  precursor in water and ethanol medium and Raoufi (2013) has prepared zinc oxide ( $\text{ZnO}$ ) nanoparticles by precipitation method from zinc nitrate and ammonium carbonate in aqueous solutions.

**Figure 2.3** SEM photograph of the nano-sized  $\text{ZnO}$  powders (Chen et al., 2008).

### **2.1.2. Mixed metal oxide nanocomposites by precipitation method**

Nowadays, the synthesis of mixed metal oxide nanocomposites has attracted much interest of researchers. These mixed oxides are attractive with respect to applications in catalysis, sensing, adsorption, energy storage, electronics and many more. The combination of 2 metals in an oxide matrix can produce materials with novel structural and/or electronic properties.

The unique properties arise due to metal-metal or metal-oxygen- metal interactions in mixed metal oxides may not be seen in single-metal oxides (Park et al., 2009).

Azhari et al. (2010) synthesized  $\text{Fe}_2\text{O}_3/\text{MgO}$  nanocomposite via a simple precipitation route in which a dispersed system containing nano-MgO flakes and nano- $\text{Fe}_2\text{O}_3$  particles was obtained. In a typical synthesis procedure, suspension of iron oxide was added to magnesium sulfate solution and then ammonia ( $\text{NH}_4\text{OH}$ , 25 wt. %) as the alkaline agent was added drop wise to the suspension with vigorous stirring to adjust pH to 11. Then, the product was washed, dried and heated at  $475^\circ\text{C}$  for 1h to convert magnesium hydroxide to magnesium oxide and finally calcined at  $600^\circ\text{C}$  to form  $\text{Fe}_2\text{O}_3/\text{MgO}$  nanocomposite. Chu et al. (2009) have synthesized  $\text{In}_2\text{O}_3\text{--SnO}_2$  nanocomposites with controllable morphologies via a precipitation method. In a typical procedure, tin (II or IV) chloride and different molar of indium (III) nitrate were dissolved in 40 mL absolute ethanol at room temperature and 40 ml of ethanol solution that contains 1.2 g KOH were slowly dripped into the mixed metal salt solution under stirring to form a precipitate. Then, the precipitate was washed, dried and calcined at  $600^\circ\text{C}$  to form of  $\text{In}_2\text{O}_3\text{--SnO}_2$  nanocomposite. They have found that variation of In/Sn ratios facilitated the modification of  $\text{In}_2\text{O}_3\text{--SnO}_2$  morphology from nanoparticles to nano-toasts and nanorods that possess ultrahigh response and selectivity to ethanol. Narkiewicz and co-workers (2008) have synthesized series of ZnO nanosized samples doped with wide range of  $\text{Fe}_2\text{O}_3$  concentration (5-95 wt. %) by precipitation from nitrate solutions using ammonia. Initially, mixture of iron and zinc hydroxides were obtained by addition of ammonia solution, proper amount of  $\text{Zn}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$  and  $\text{Fe}(\text{NO}_3)_3 \cdot 4\text{H}_2\text{O}$  in water. Then, the obtained hydroxides were filtered, dried and calcined at  $300^\circ\text{C}$  for 1 h. A series of samples containing from 5- 95 wt % of  $\text{Fe}_2\text{O}_3$  was obtained using this method. From XRD result it was observed that, different phases are formed with respect to  $\text{Fe}_2\text{O}_3$  concentration such as:  $\text{ZnFe}_2\text{O}_4$  phase for 5-10 wt %  $\text{Fe}_2\text{O}_3$  concentration, composite  $\text{ZnO-ZnFe}_2\text{O}_4$  for 30 & 40 wt %  $\text{Fe}_2\text{O}_3$  concentration, again  $\text{ZnFe}_2\text{O}_4$  phase for 50-80 wt %  $\text{Fe}_2\text{O}_3$  concentration and  $\text{Fe}_2\text{O}_3$  phase for 90 & 95 wt %  $\text{Fe}_2\text{O}_3$  concentration. Uniform MgO/CNT nanorods were fabricated by Taleshi and Hosseini (2012) using precipitation method. In this work, they used carbon nanotubes (CNTs) as a support for synthesis, size control, and morphology of magnesium oxide. The morphology of MgO nanoparticles were varying by changing the weight percent of CNTs in the solution. Basu and Ghosh (2013) synthesized nano-structured iron(III)–cerium(IV) mixed oxide by a facile precipitation method. In a typical procedure, NaOH solution was added drop wise to ammonium cerium (IV) nitrate and ferric chloride solutions

with continuous stirring to raise pH 9.3 ( $\pm 0.3$ ). The obtained gel-like precipitate was allowed to stand for two days, then washed and dried at 100 °C in an air oven. The dried product was grinded using mortar and pestle followed by sieving to separate the agglomerates. From figure 2.4 TEM image, it is observed that the bimetal mixed oxide contained agglomerated crystalline nano-particles of dimension 10-20 nm. The synthesized iron(III)–cerium(IV) mixed oxide nanomaterial was regarded as an excellent adsorbent for removal of carcinogenic arsenic ion from aqueous solution.

**Figure 2.4** TEM image of nano-structured iron(III)–cerium(IV) mixed oxide (Basu and Ghosh, 2013).

Cao et al. (2014) have fabricated  $\text{Fe}_3\text{O}_4$ /chitosan nanoparticles with quasi-spherical or ellipsoidal in shape and about 7 nm in average diameter by a simple reduction–precipitation method through partial reduction of  $\text{Fe}^{3+}$  before the formation of  $\text{Fe}_3\text{O}_4$  nanoparticles. Typically,  $\text{FeCl}_3$  solution was added into chitosan solution under continuous stirring for 1 h. Then,  $\text{Na}_2\text{SO}_3$  solution was added into the yellow colloidal solution of chitosan, and the color of the mixed solution immediately changed from yellow to red and again from red to yellow. Then mixed solution was poured quickly into ammonia solution under vigorous stirring at room temperature to form black precipitate suspension. After that, cross-linking agent epoxy chloropropane was added to the black suspension solution in order to stabilize  $\text{Fe}_3\text{O}_4$ /CS NPs in acid solution. The prepared  $\text{MFe}_3\text{O}_4$ /CS NPs exhibited high adsorption capacity and removal rate for brilliant red X-3B dye. Again in 2015, Cao et al. have synthesized  $\text{Cu}_2\text{O}$ /chitosan– $\text{Fe}_3\text{O}_4$  nanocomposite ( $\text{Cu}_2\text{O}/\text{CS}-\text{Fe}_3\text{O}_4$  NC) with large specific surface

areas and special dimodal pore structure via a facile one-step precipitation-reduction process by using magnetic chitosan chelating copper ions as precursor. Initially, they have prepared CS-Fe<sub>3</sub>O<sub>4</sub> by using their previous method. The as-prepared CS-Fe<sub>3</sub>O<sub>4</sub> NPs were dissolved acid solution and CuSO<sub>4</sub>·5H<sub>2</sub>O and glucose were added into above colloidal solution under continuous stirring until they fully dissolved. The obtained mixture was then kept in water bath at 54 °C and pH value was adjusted to 10. Then, cross-linking agent epoxy chloropropane was added to stabilize Cu<sub>2</sub>O/CS-Fe<sub>3</sub>O<sub>4</sub> NCs in acid solution. The prepared Cu<sub>2</sub>O/CS-Fe<sub>3</sub>O<sub>4</sub> NCs were used as an effective photocatalyst for decolorization of reactive brilliant red X-3B (X-3B) under visible light irradiation and it was observed that the decolorization rates of X-3B were still above 87 % after five reaction cycles. Synthesis of mixed metal ferrites is also possible through precipitation method. Shinde et al. (2008) have prepared polycrystalline cubic spinel structured ferrites with general formula Ni<sub>1-x</sub>Zn<sub>x</sub>Fe<sub>2</sub>O<sub>4</sub> (x=0, 0.2, 0.4, 0.6, 0.8, and 1.0) using oxalate precipitation method. They observed that the average crystallite size of the ferrites were in the range 27.59–31.49 nm.

## 2.2. Hydrothermal Method

In this method heterogeneous reaction is carried out in the presence of aqueous solvents under high pressure and temperature conditions using a hydrothermal vessel. Hydrothermal reaction is normally accompanied in steel pressure vessels called autoclaves (hydrothermal vessel) with or without Teflon liners under controlled temperature and/or pressure in aqueous solutions. The process involves elevation of temperature above the boiling point of water at the pressure of vapour saturation. This method is cost-effective and easy route for preparing various metal hydroxides and oxy-hydroxides at low temperature and in a short reaction time and widely used for the production of small particles in the ceramics industry (Sahin, 2004; Chen et al., 2006).

**Advantages of hydrothermal method:** The method is useful for synthesis of low temperature phases and metastable compounds. Compounds having elements with an unusual oxidation state can be synthesized by this method. Nanopowders are formed directly from the solution. It is possible to control particle size and shapes by using different starting materials and hydrothermal conditions. Monodispersed and highly homogeneous metal oxide nanomaterials (Nanoparticles/nanorods) can be prepared by this method. The method acts as one of the most attractive techniques for processing nanocomposite and nano-hybrid

materials. Less time consumption, rapid growth rates (because of the rapid diffusion processes), low cost, high product purity, environment friendly and the ability to control the particle size are the other strengths of this method (Byrappa and Adschiri; 2007; Sahin, 2004; Wojciech et al., 2006; Vivekanandhan, 2010).

**Disadvantages of hydrothermal method:** The method includes the need of expensive autoclaves. Observing the crystal as it grows is not possible. Hydrothermal slurries are potentially corrosive. Accidental explosion of the high pressure vessel cannot be ruled out (Vivekanandhan, 2010; Byrappa and Adschiri; 2007).

### **2.2.1. Metal oxide nanomaterials by hydrothermal method**

Properties of metal oxide nanomaterials are widely depend on their size, shape and morphologies. Nowadays, synthesis of metal oxide nanomaterials with controlled shape and methodologies and surface modification has attracted increasing attention in biological, electronics, and environmental applications including chemical sensing, photocatalytic degradation, separation, and purification of toxic molecules from the matrices. Development simple and reliable synthetic techniques for low-dimensional metal oxide nanostructures with designed chemical components and well-ordered morphologies can easily achieved by hydrothermal method.

Li et al. (2008) have synthesised Uniform  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods with high aspect ratios in large scale by a simple and direct 1, 2-propanediamine-assisted hydrothermal method. In this method, they mixed FeCl<sub>3</sub> solution and 1, 2-propanediamine with vigorous stirring and then transferred the above solution into Teflon-lined stainless-steel autoclave for hydrothermal treatment at 180 °C for 16 h. They have reported the formation of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods by varying the 1, 2-propanediamine content, pH value, concentration of FeCl<sub>3</sub> and reaction temperature. By this method they found high yield rod like products with a diameter of 30–40 nm and length of 400–600 nm (figure 2.5). Pradhan and Parida (2011) have synthesized  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods and nano-hexagons by facile hydrothermal method. In a typical experiment, stoichiometric amounts of (NH<sub>4</sub>)<sub>2</sub>HPO<sub>4</sub> were added to aqueous solution of FeCl<sub>3</sub>.6H<sub>2</sub>O, under vigorous stirring to form a yellow homogeneous solution. Then the solution was then sealed into a Teflon-lined autoclave, followed by hydrothermal treatment at 220 °C for 12, 24 and 36 h. They also prepared  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanostructures by adding surfactant SDS and PEG following the same method. It is observed that addition of SDS doesn't affect the surface

structure of the nanorod. On the other hand, when the system was added with PEG, hexagonal-shaped nanoparticles were obtained.

**Figure 2.5** SEM images of the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods: (a) low-magnification SEM image and (b) high-magnification SEM image (Li et al., 2008).

Xiao and co-workers (2012) have successfully synthesized single-crystalline  $\alpha$ -FeOOH nanorods with a length of 400–700 nm and a diameter of 20–80 nm via a facile template-free hydrothermal method using Fe(NO<sub>3</sub>)<sub>3</sub>·9H<sub>2</sub>O and KOH as the starting materials. The  $\alpha$ -FeOOH precursors were calcined at 350 °C in air and at 500 °C in nitrogen, respectively to form single-crystalline mesoporous  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and Fe<sub>3</sub>O<sub>4</sub> nanorods, with large specific surface area and porosity. Similarly,  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods of average ~40 nm in diameter and ~400 nm in length were successfully fabricated by Lin and co-workers in 2011 through hydrothermal method. They have added iron chloride hexahydrate (FeCl<sub>3</sub>·6H<sub>2</sub>O) solution to 1, 2-diaminopropane (C<sub>3</sub>H<sub>10</sub>N<sub>2</sub>) at a 1:1 volume ratio with continuous stirring 15 min. Then the solution was transferred to a Teflon-lined stainless steel autoclave and heated to 220 °C for 20 h. TEM image of the prepared nanorod hydrothermal method is shown in figure 2.6. This indicates the periodic lattice fringes across the entire nanorod and each of the nanorods is a monocrystal and the calculated lattice spacing is 3.65 Å, corresponding to the (012) plane of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>.

**Figure 2.6** TEM images of a single  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorod (a) at a low magnification (b) at a medium magnification, and (c) at a high magnification. The white arrows and solid lines in panel c indicate two consecutive lattice fringes (Lin et al., 2011)

Other 1D metal oxide nanostructures such as; MgO, CuO, SnO<sub>2</sub>, ZnO were also synthesized by hydrothermal method. Wen et al. (2013) have synthesized mesoporous rhombic ZnO nanorod arrays by a facile fluorine-mediated hydrothermal method. In a typical procedure, 4 mmol Zn(NO<sub>3</sub>)<sub>2</sub>·6H<sub>2</sub>O, 16 mmol NH<sub>4</sub>F and 8 mmol hexamethylenetetramine (C<sub>6</sub>H<sub>12</sub>N<sub>4</sub>) were dis-solved in 40 ml water. After stirring, the homogeneous solution was transferred into a 50 ml Teflon-lined stainless steel autoclave and then a piece of titanium foil was immersed. The autoclave was maintained at 95 °C for 24 h and obtain the precursor Zn(OH)F were converted to ZnO via thermal decomposition at 450 °C in air for 4 h. From SEM images (figure 2.7), It is observed that in the absence of NH<sub>4</sub>F, the surface of the substrate is covered with hexagon-shaped nano-rods of diameter more than 500 nm; for 4 mmol NH<sub>4</sub>F, hexagon-shaped nanorods and rhombic nano-wires coexist in the product and for 8 mmol, rhombic nanowires are the only morphology while the hexagon-shaped NRs disappear entirely; again for 16 mmol of NH<sub>4</sub>F, the morphology retains a rhombus-shaped architecture, and shows complete nanorods. The prepared ZnO nanorod array based gas sensor showed high performance for ethanol detection.

**Figure 2.7** SEM images of ZnO nanostructures with different concentrations of NH<sub>4</sub>F: (a) 0 mmol, (b) 4 mmol, (c) 8 mmol and (d) 16 mmol (Wen et al., 2013)

Jiang and co-workers (2013) have synthesized SnO<sub>2</sub> nanorods with the diameter of 25 nm and the length of 200-300 nm by a facile one-step hydrothermal route. NaOH solution was added into Na<sub>2</sub>SnO<sub>3</sub>·3H<sub>2</sub>O aqueous solution with continuous stirring, and then absolute ethanol was slowly added into the mixed solution followed by transformation into a Teflon-lined autoclave and kept at 210 °C for 48 h. After cooling to room temperature, the resulting precipitates were collected and washed and dried to form SnO<sub>2</sub> nanorod. Dhaouadi et al. (2011) have synthesized Magnesium hydroxide (Mg(OH)<sub>2</sub>) nanorods with a diameter

between 10 and 40 nm and a length of up to 300 nm by a simple and facile hydrothermal method in the presence of cetyltrimethylammonium bromide (CTAB) as a surfactant. In a typical procedure, they have dispersed commercial MgO powder in aqueous solution of CTAB with sufficient stirring and the solution was transferred into a Teflon-lined stainless steel autoclave and maintained at 200 °C for 24 h. The resulted powders were filtered, washed and dried in vacuum at 80 °C for 2h to form Mg(OH)<sub>2</sub> nanorod. The Mg(OH)<sub>2</sub> nanorods were found to exhibit higher antibacterial efficiency against several tested bacterial strains such as: *Staphylococcus aureus* ATCC 6538, *Enterococcus faecalis* ATCC 29212, *Enterococcus faecium* ATCC 19434, *Bacillus cereus*, *Bacillus subtilis*, *Staphylococcus faecalis* and *Streptococcus B* (*Streptococcus agalactiae*).

Similarly, CuO nanoneedles were synthesized by Dar et al. (2008) using hydrothermal method. They have mixed NaOH solution with Cu(NO<sub>3</sub>)<sub>2</sub>·3H<sub>2</sub>O solution and then the mixed solution was transferred into a Teflon-lined stainless steel autoclave maintained at a temperature of 120-180 °C for 20-60 h followed by cooling to room temperature. The obtained black precipitate was washed and dried at 75 °C for 6 h to form CuO nanoneedles with typical diameters of the stem part and the sharp ultrathin nanotip that range between 70±10 and 15±5 nm, respectively, and the whole length of nanoneedle appears to be 500 nm to 1 µm. The authors have studied the magnetic properties of CuO nanoneedles using a superconductor quantum interference device (SQUID) magnetometer, and found a ferromagnetic behavior of the CuO nanoneedles with coercivity of 42 Oe at 3 K. The synthesized CuO nanoneedles may be implicated to various applications such as drug delivery, magnetic resonance imaging and field emission devices.

Recently, porous α-Fe<sub>2</sub>O<sub>3</sub> nanospheres with diameter about 50 nm have been successfully prepared by Deng et al. (2013) using a microwave-assisted hydrothermal method. In a typical synthesis, 0.5 mmol of FeCl<sub>2</sub>·4H<sub>2</sub>O and 1.5 mmol of sodium acetate were dissolved into 40 ml of distilled water, and then heated by microwave method with power of 800 W for 10 min. Finally, the product was cooled, washed, dried and annealed at 500 °C for 2h. The porous α-Fe<sub>2</sub>O<sub>3</sub> nanosphere-based sensor offered a fast response, superior sensitivity and outstanding selectivity towards H<sub>2</sub>S due to its intrinsic characteristics, porous structure and nanoscale size. Hu et al. (2007) have developed a fast and economical route based on an efficient microwave-assisted hydrothermal process to synthesize self-assembled hierarchical α-Fe<sub>2</sub>O<sub>3</sub> nanoarchitectures on a large scale. 30 mL of an aqueous K<sub>3</sub>[Fe(CN)<sub>6</sub>] solution was sealed in a Teflon-lined double-walled digestion vessel and treated at a controllable temperature for 10

min in a microwave digestion system, thereafter the product was collected, washed with deionized water and absolute ethanol, and dried in a vacuum at 80°C for 4 h. Figure 2.8 clearly reveals that the product is composed of a large quantity of uniform dendritic architectures with many hierarchical fractals with six symmetric trunks, forming “star-like” architectures.

**Figure 2.8** (a) Low-magnification and (b, c) high-magnification SEM images of the hierarchical  $\alpha\text{-Fe}_2\text{O}_3$  nanoarchitectures (Hu et al., 2007)

Single-crystalline  $\alpha\text{-Fe}_2\text{O}_3$  hollow nanocrystals from nanotube to nanoring have been successfully synthesized by Fan et al. (2009) using a facile hydrothermal method. They have used  $\text{FeCl}_3$  and  $\text{NH}_4\text{H}_2\text{PO}_4$  precursors as solutions followed by hydrothermal treatment at 220 °C for 60 h. The red precipitate obtained was centrifuged, washed and dried under vacuum at 80 °C to form the hollow  $\alpha\text{-Fe}_2\text{O}_3$  nanocrystals. They have also studied the size- and shape-dependent optical response of these hollow nanocrystals using steady absorption and femtosecond OHD-OKE measurements. Ma et al. (2010) have reported size- and shape-controlled fabrication of  $\alpha\text{-Fe}_2\text{O}_3$  via a facile template-free hydrothermal route by simply changing only reaction time and solvent. In this report,  $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$  was dissolved in ammonia-water under mild stirring and the brown precipitate floccules immediately formed were transferred into a Teflon-lined stainless steel autoclave followed by heating to 180 °C for 8 h to form red precipitate of  $\alpha\text{-Fe}_2\text{O}_3$  nanoparticles of 80 nm in diameter. While the reaction time was continued to 24 h, nanoparticles-aggregated  $\alpha\text{-Fe}_2\text{O}_3$  microcubes with edge about 1  $\mu\text{m}$  could be obtained. The SEM, TEM, and HR-TEM images of the prepared nanoparticles and microcubes were given in figure 2.9. They have also done magnetic

measurement of the prepared nanostructures. The magnetic hysteresis measurements demonstrated that the as-obtained  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanostructures show structure-dependent magnetic properties.

**Figure 2.9** (a) SEM, (b) TEM, and (c) HRTEM images of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanopolyhedra; (d) SEM image of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles; (e and f) SEM images of nanoparticles-aggregated  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> microcubes (Ma et al., 2010).

Other metal oxide nanostructure such as: MgO, ZnO and CuO with different morphologies also have been synthesized by hydrothermal method. Li et al. (2012) have synthesized mesoporous MgO nanoplate adsorbent with mesopore diameter of 10-20 nm by hydrothermal method using Dioctylsulfosuccinate sodium surfactant (AOT) as a structure-directing agent. In a typical synthesis, MgO was added into deionized water containing different concentrations of AOT surfactant with ultrasonically stirred for 10 min followed by hydrothermal treatment for 24 h at 160 °C. The white Mg(OH)<sub>2</sub> precipitate was calcined at 600 °C for 3 h in air to produce porous MgO samples. The prepared MgO nanomaterials were used as adsorbents for removal of three typical azo dye pollutants, Congo red, Methyl orange and Sudan III. Because of their higher specific surface area and porous structure, the MgO materials exhibited a satisfactory adsorptive property with maximum adsorption capacities of 588, 370 and 180 mg/g for Congo red, Methyl orange and Sudan III, respectively.

In 2011 Xie and co-workers have successfully synthesized flower-like and sheet-like ZnO structures by hydrothermal method. First aqueous precursor was prepared by zinc nitrate hexahydrate (Zn(NO<sub>3</sub>)<sub>2</sub>·6H<sub>2</sub>O) and hexamethylenetetramine (HMT) and was transferred into

a teflon-lined stainless steel autoclave. A piece of substrate, coated with pre synthesized ZnO seeds, was placed in the bottom of the autoclave. The reaction pressure was 5 MPa and the temperature was 150 °C. Finally, the substrate was thoroughly washed with deionized water to eliminate residual salts, and dried in air. The obtained ZnO nanostructure was consisting of numerous flower-like aggregates made up of many thin nanosheets with an average about 80 nm in thickness and 500 nm in length. The obtained nanomaterials were applied as photocatalyst for degradation of Methyl orange from aqueous solution under UV light irradiation. The results indicated that the sheet-like ZnO nanostructures exhibited higher photodegradation efficiencies under UV light irradiation than flower-like ZnO structures due to the blue shift of the bandgap.

### **2.2.2. Mixed metal oxide nanocomposites by hydrothermal method**

Metal oxide nanocomposite cannot be considered as a simple superposition of the properties of individual components due to the strong surface interactions between the closely packed nanoparticles in the multiple metal oxide systems. Here mixing of two or more metal oxide phases can be controlled on both the molecular and the nanoscale. These metal oxides are attractive with respect to applications in catalysis, adsorption, sensing, energy storage, electronics and many more. Numerous investigations are being carried out for production of mixed metal oxide nanocomposite in recent past few years.

Hierarchical  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>/SnO<sub>2</sub> composites were synthesized by a low-cost and environmentally friendly hydrothermal strategy by Sun et al. (2013). Initially, they have synthesized SnO<sub>2</sub> hierarchical nanostructures by using SnSO<sub>4</sub> and Na<sub>3</sub>C<sub>6</sub>H<sub>5</sub>O<sub>7</sub>·2H<sub>2</sub>O in alcohol-water solution followed by hydrothermal treatment at 80 °C for 12 h. For synthesis of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>/SnO<sub>2</sub> composites, the above prepared SnO<sub>2</sub> powder was dispersed in deionized water under magnetic stirring and FeCl<sub>3</sub>·6H<sub>2</sub>O and Na<sub>2</sub>SO<sub>4</sub>·10H<sub>2</sub>O were added into the above solution. After that, the formed suspension was transferred into a Teflon-lined stainless-steel autoclave and heated at 120 °C for 8 h. The resulting product was centrifuged, washed, dried and finally annealed at 500 °C for 2 h to form hierarchical  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>/SnO<sub>2</sub> composites. The FESEM and TEM results revealed that the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods grew epitaxially on the surface of SnO<sub>2</sub> nanosheets. The diameter and length of the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods were about 10 and 80 nm, respectively, and the thickness of the SnO<sub>2</sub> nanosheets was about 15 nm. They have studied the acetone sensing properties of the prepared nanocomposite and have reported that hierarchical  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>/SnO<sub>2</sub> nanostructures exhibited an enhanced acetone sensing properties compared with the primary SnO<sub>2</sub> nanostructures. Wang et al. (2012) have synthesized a novel

hierarchical  $\text{SnO}_2\text{-Fe}_2\text{O}_3$  heterostructure, consisting of a micron-sized primary  $\text{SnO}_2$  nanosheet base and sub-10 nm diameter  $\text{Fe}_2\text{O}_3$  nanorod branches grown on the nanosheet surface by a facile two-step hydrothermal growth method. Initially,  $\text{SnO}_2$  nanosheets were synthesized by a modified hydrothermal method using  $\text{SnCl}_2\cdot 2\text{H}_2\text{O}$  and  $\text{NaOH}$  precursor solutions at  $160^\circ\text{C}$  for 14 h. For synthesis of  $\text{SnO}_2\text{-Fe}_2\text{O}_3$  heterostructures, the previously prepared  $\text{SnO}_2$  nanosheet powder was placed in a Teflon-lined autoclave containing a solution consisting of  $\text{FeCl}_3$  and  $\text{Na}_2\text{SO}_4$  and incubated in an oven at  $120^\circ\text{C}$  for 8 h. Then the products obtained were centrifuged, washed and further heated in air at  $450^\circ\text{C}$  for 2 h. From SEM images, it is observed that  $\text{SnO}_2$  nanosheets have an average edge length of 500 nm to 1  $\mu\text{m}$  and a uniform thickness of 5 nm, and are assembled into flower-like aggregates (figure 2.10). It is observed from the figure that a layer of short nanorod branches were grown on each basal surface of composite nanosheets (given in Figure 2.10 c and d). These nanorod branches have a relatively uniform length of 50-100 nm. The hierarchical  $\text{SnO}_2\text{-Fe}_2\text{O}_3$  heterostructures can be used as lithium-ion battery anodes made with high initial discharge capacity of  $1632\text{ mA h g}^{-1}$  at  $400\text{ mA g}^{-1}$ , which will retain at  $325\text{ mA h g}^{-1}$  after 50 cycles.

**Figure 2.10** SEM images of (a) pristine  $\text{SnO}_2$  nanosheets; (b) undecorated  $\alpha\text{-Fe}_2\text{O}_3$  nanorods; and (c and d) hierarchical  $\text{SnO}_2\text{-Fe}_2\text{O}_3$  heterostructures (Wang et al., 2012).

More recently, Kaneti et al. (2015) have reported a facile hydrothermal strategy for the synthesis of novel ternary  $\alpha\text{-Fe}_2\text{O}_3\text{-ZnO-Au}$  nanocomposites under mild conditions, through surface coating of ZnO and Au nanoparticles (NPs) on  $\alpha\text{-Fe}_2\text{O}_3$  nanorods. They have schematically described the three steps in figure 2.11. According to them, porous  $\alpha\text{-Fe}_2\text{O}_3$

nanorods achieved by the calcination of  $\alpha$ -FeOOH nanorods were used as a template to deposit ZnO NPs using hydrothermal technique. Then, an in situ reduction of HAuCl<sub>4</sub> was done to decorate Au NPs on the surfaces of the deposited ZnO NPs and on the inner and outer parts of the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods. The ternary  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-ZnO-Au nanocomposites were found to show higher sensitivity/responses with lower optimum operating temperature towards n-butanol and acetone compared to single  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and binary  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-ZnO.

Niu et al. (2010) have synthesized branched SnO<sub>2</sub>/ $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> composite nanoheterostructures by a low-cost and environmentally friendly hydrothermal strategy, through crystallographic-oriented epitaxial growth of the SnO<sub>2</sub> nanorods onto the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanospindles and nanocubes, respectively. Initially, they have prepared  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> precursors of nanospindles and nanocubes by hydrothermal method. For SnO<sub>2</sub>/ $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> precursors were dispersed in the Sn(OH)<sub>6</sub> dilute aqueous solution with ultrasonication for 10 min followed by hydrothermal treatment at 220 °C for various durations. The resulting products were centrifuged, washed and dried in vacuum. The SnO<sub>2</sub>/ $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> semiconductor nanoheterostructures exhibited excellent visible light or UV photocatalytic abilities; which was superior to  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> precursors, due to the effective electron-hole separation at the SnO<sub>2</sub>/ $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> interfaces. Similarly, El-Molla and co-workers (2015) have synthesized Fe<sub>2</sub>O<sub>3</sub>/MgO systems by the incipient impregnation, co-precipitation, and hydrothermal techniques. In the wet impregnation method, Mg(OH)<sub>2</sub> was impregnated into iron nitrate and

dissolved in smallest possible volume of double-distilled water. Then co-precipitation of iron and magnesium was achieved by addition of aqueous ammonia solution ( $\text{NH}_4\text{OH}$ ) to iron and magnesium nitrates at 25 °C and pH 8. The obtained precipitate was washed and dried at 110 °C. Then a suspension of the obtained precipitate was taken in a Teflon-lined autoclave and treated at 200 °C for 1 h. The solids obtained were calcined at 500-900 °C to form  $\text{Fe}_2\text{O}_3/\text{MgO}$  nanocomposite. The nanocomposite contained the nanosized MgO phase in addition to the  $\text{MgFe}_2\text{O}_4$  phase. The prepared nanocomposite was used as an efficient catalyst for decomposition of  $\text{H}_2\text{O}_2$ . Mahapatra et al. (2013) have synthesized mixed iron and aluminium oxide ( $\text{Fe}_2\text{O}_3\text{-Al}_2\text{O}_3$ ) nanocomposites by hydrothermal method, and studied their adsorption behavior towards decolorization of Congo red dye from an aqueous system. In their work,  $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$  and  $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$  salts were taken in a molar ratio of 1:1 and were mixed in distilled water. They have added a mixed solution of NaOH and  $\text{NH}_4\text{OH}$  drop wise to the above salt solution up to pH 5.6. Then the obtained green precipitate was transferred into a Teflon cupped pressure pot and treated 180 °C for 6 h. The obtained deep yellow powder was further calcined at 500 °C and 1000 °C, to form mixed  $\text{Fe}_2\text{O}_3\text{-Al}_2\text{O}_3$  nanocomposites. From XRD results they have observed the formation of mixed  $\gamma\text{-Fe}_2\text{O}_3\text{-Al}_2\text{O}_3$  phase and  $\alpha\text{-Fe}_2\text{O}_3\text{-Al}_2\text{O}_3$  phase for calcination temperatures 500 and 1000 °C, respectively. They have used the three different nanocomposites as adsorbents for removal of Congo red dye molecules and found that the  $\gamma\text{-Fe}_2\text{O}_3\text{-Al}_2\text{O}_3$  exhibited superb adsorption efficiency with maximum adsorption capacity of 498 mg/g.

Chang et al. (2013) have demonstrated a facile and low-cost synthesis of the ZnO/CuO nanocomposites by two-step hydrothermal methods. Initially they have synthesized pure ZnO nanostructures by hydrothermal method using  $\text{ZnCl}_2$  solution in water and isopropanol. The pH of the solution was maintained to 11 using KOH and the hydrothermal temperature was 120 °C for 10 h. For synthesis of ZnO/CuO nanocomposites, they have redispersed the as-prepared ZnO nanostructures into water and added copper(II) acetate with the solution under ultra-sonication. Then, hydrothermal reaction was carried out at 120°C for 8 h and the ZnO/CuO nanocomposites were synthesized and collected through washing, centrifugation and drying. The prepared ZnO nanoplates have smooth surface and high crystallinity with sizes in the range 100~300 nm and the thicknesses in the range 40~50 nm. In ZnO/CuO nanocomposites, it is found that the CuO nanopariticules with 300~500 nm are well-mixed with ZnO uniformly in the nanocomposites. The photocatalytic properties of the as-synthesized ZnO/CuO nanocomposites for degradation of methylene blue dye have been

investigated under UV irradiation and the experimental results showed that MB can be degraded completely within 15 min and its photodegradation efficiency was six times faster than that of pure ZnO.

Wang et al. (2014) have synthesized hierarchically structured magnetic  $\text{MnO}_2/\text{ZnFe}_2\text{O}_4$  hybrid materials and studied their performance in heterogeneous activation of peroxymonosulfate. Initially, they have synthesized  $\text{ZnFe}_2\text{O}_4$  nanoparticles via a modified hydrothermal method. For synthesis of  $\text{ZnFe}_2\text{O}_4/\text{MnO}_2$  hybrid structures, they have dispersed the prepared  $\text{ZnFe}_2\text{O}_4$  in water by sonication followed by addition of  $\text{KMnO}_4$  and  $\text{HCl}$  to the suspension under vigorous stirring. Then the solution was transferred into a Teflon-lined stainless steel autoclave and treated at 100 and 140 °C for 12 h. The SEM images (figure 2.12) of the sample prepared at 100 °C suggested a uniform corolla-like structure consisting of microsphere/nanosheet hierarchical nanostructures with an average diameter around 2  $\mu\text{m}$ , on the other hand the sample prepared at 140 °C contained hierarchical sea-urchin shaped microstructure with a diameter of 3-4  $\mu\text{m}$ , made of straight tetragonal nanorods with a uniform diameter of 30-40 nm. The  $\text{ZnFe}_2\text{O}_4/\text{MnO}_2$  nanocomposites prepared at 140 °C have shown enhanced photocatalytic efficiency towards degradation phenol than  $\text{ZnFe}_2\text{O}_4/\text{MnO}_2$  nanocomposites prepared at 100 °C,  $\text{ZnFe}_2\text{O}_4$  nanoparticles and commercial  $\text{MnO}_2$ . Hu et al. (2015) have synthesized novel starfish-shaped porous  $\text{Co}_3\text{O}_4/\text{ZnFe}_2\text{O}_4$  hollow nanocomposite by a facile and stepwise hydrothermal approach, utilizing metal-organic frameworks as precursors and sacrificial templates. Previously prepared porous  $\text{Co}_3\text{O}_4$  nanocages were dissolved in DMF-ethanol mixture solution and sonicated for 30 min at room temperature. Then,  $\text{Fe}(\text{acac})_3$ ,  $\text{Zn}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$  and  $\text{H}_2\text{BDC}$  were added to the above solution under sonication. The mixed solution was transferred to a 50 mL Teflon autoclave and was heated at 100 °C for 6 h to form starfish-shaped  $\text{Co}_3\text{O}_4/\text{Fe}^{\text{III}}\text{-MOF-5}$  hollow nano-composites. The starfish-shaped  $\text{Co}_3\text{O}_4/\text{ZnFe}_2\text{O}_4$  hollow nanocomposite was synthesized by heating the as-synthesized  $\text{Co}_3\text{O}_4/\text{Fe}^{\text{III}}\text{-MOF-5}$  in the tube furnace in air at 500 °C for 2 h. From TEM image (figure 2.13), they have observed that the  $\text{Co}_3\text{O}_4/\text{ZnFe}_2\text{O}_4$  nanocomposite was starfish-shaped hollow structure, while the nanotubes become highly porous, consisting of numerous  $\text{ZnFe}_2\text{O}_4$  nanocrystals of 10 nm. Magnetic measurements show that the system presents a large coercivity and high squareness (at 1.8 K,  $H_c = 884$  Oe and  $M_r/M_s = 0.52$ ) with respect to the individual components.

**Figure 2.12** SEM images of  $\text{ZnFe}_2\text{O}_4/\text{MnO}_2$  samples prepared at (A) and (B) 100 °C, (C) and (D) 140 °C (Wang et al., 2014).

**Figure 2.13** TEM images of (a)  $\text{Co}_3\text{O}_4/\text{ZnFe}_2\text{O}_4$  hollow nanocomposites, (b) a single  $\text{ZnFe}_2\text{O}_4$  nanotube, (c) High resolution TEM lattice image of a  $\text{ZnFe}_2\text{O}_4$  nanoparticle, and (d) SAED patterns of the  $\text{ZnFe}_2\text{O}_4$  nanotube (Hu et al. 2015).

Similarly, Fu et al. (2014) have reported Ti-doped  $\alpha\text{-Fe}_2\text{O}_3$  nanorod arrays prepared by a facile approach and implemented them as photoanodes for photoelectrochemical water

splitting. They have sealed an aqueous solution of ferric chloride and sodium nitrate in a teflon-lined autoclave. Again, fluorine doped tin oxide (FTO)-coated glass of  $1 \times 2.5$  cm was cleaned with deionized water, ethanol, acetone, ethyl acetate and was placed in the liner with the FTO side facing the wall of the liner. Then, different volume percentage of titanium tetrachloride ( $\text{TiCl}_4$ ) with ethanol solution was added to teflon-lined. After hydrothermal treatment at  $100^\circ\text{C}$  for 12 h, the yellow films formed on the FTO substrates were thoroughly rinsed with deionized water and transferred to a furnace and were annealed at  $550^\circ\text{C}$ . The Ti-doped  $\alpha\text{-Fe}_2\text{O}_3$  nanorod arrays showed enhanced photoelectrochemical activity for water splitting due to the improved donor density and reduced recombination of the electron-hole pairs. Ang et al. (2013) have synthesized ZnO-CuO corn-like composites via a simple two step solution-based method. First, they have synthesized ZnO nanorods on a glass substrate by the hydrothermal method and then they have deposited CuO on ZnO NRs photochemically using ultraviolet (UV) light irradiation at room temperature. They have reported that ZnO-CuO nanocomposites show an excellent improvement in photocatalytic characteristics compared to bare ZnO NRs for degradation of Methyl orange under UV and solar light irradiation.

### 2.3. Reflux Method

Reflux method is also another important wet chemical method used for the synthesis of metal oxide nanomaterials. In this method, generally a condenser is fitted to the boiling flask and is clamped in an upright position (called as reflux position) and cooling water is circulated to cause the vapours to condense as they rise up the condenser. Hence the solvent or reagent loss due to evaporation is prevented. This reaction follows the hydrolysis and condensation reaction of metal salt precursors to form the corresponding metal oxides nanomaterials.

**Advantages of reflux method:** This technique normally involves relatively lower reaction temperatures as compared to hydrothermal method with simpler operations, higher yield, lower cost, environment friendly and can be easily controlled (Genuino et al., 2012; Qiu et al., 2011). The method is efficient to achieve crystalline phase at a lower temperature with low aggregation (Bandgar et al., 2011).

**Disadvantages of reflux method:** Nanomaterials with rather large and non-uniform particle size and shapes are formed by this method, which restrict further improvement in the performance of the products (Genuino et al., 2012; Qiu et al., 2011).

### 2.3.1. Metal oxide nanomaterials by Reflux method

The reflux method is an economical and environment friendly, which can be performed at relatively low temperature ( $<100\text{ }^{\circ}\text{C}$ ) without the use of any expensive equipment. Large scale production of metal oxide nanomaterials with well-defined size and shape is feasible by this method. Mageshwari et al. (2015) have synthesized flower-shaped hierarchical CuO microspheres consisting of interpenetrating nanosheets by reflux condensation method without using any surfactant or templates. In a typical synthesis procedure,  $\text{NH}_4\text{OH}$  solution was injected to a homogeneous blue color solution of  $\text{Cu}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$  and then refluxed at  $100\text{ }^{\circ}\text{C}$  for 12 h. The resulting black precipitate was centrifuged, washed and dried in air at  $100\text{ }^{\circ}\text{C}$  for 2 h to form single phase CuO with monoclinic crystal structure. They have applied the CuO microspheres for photodegradation of methyl orange (MO) and methylene blue (MB) dyes in the presence of hydrogen peroxide under UV light irradiation and found that the CuO hierarchical architecture possesses good photocatalytic activity towards MO and MB dyes. Ahmad et al. (2013) have reported the synthesis of copper oxide nanoparticles by reflux method. In a typical synthesis process, copper acetate solution was mixed with acetic acid and then slowly heated in a three-necked refluxing pot under stirring. When the temperature reached at  $90^{\circ}\text{C}$ , NaOH was added to form black coloured precipitates of CuO nanoparticles with average crystalline size of 5 nm. In 2004, Woo et al. have reported the synthesis of maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ) and magnetite ( $\text{Fe}_3\text{O}_4$ ) nanoparticles by thermal decomposition of  $\text{Fe}(\text{CO})_5$  using reflux method. They have injected  $\text{Fe}(\text{CO})_5$  into a mixture of octyl ether and oleic acid at  $100\text{ }^{\circ}\text{C}$ . The resulting mixture was slowly heated and refluxed for 2 h, followed by cooling to room temperature, aerated for 14 h at  $80\text{ }^{\circ}\text{C}$ , and then refluxed for 2 h to form  $\gamma\text{-Fe}_2\text{O}_3$  nanoparticles. Similarly, by varying molar ratio of  $\text{Fe}(\text{CO})_5$  to oleic acid, they have also synthesized  $\text{Fe}_3\text{O}_4$  nanoparticles. Bose et al. (2002) have reported on the synthesis of nanocrystalline tin oxide ( $\text{SnO}_2$ ) materials with average grain size in the range of 20 nm by using reflux condensation technique. Tin chloride solution was hydrolyzed for 144 h and then neutralized with ammonia solution in a flask fitted with a reflux condenser. After that the resulting precipitates were washed, dried and annealed at 600 and  $900\text{ }^{\circ}\text{C}$  to form nanocrystalline  $\text{SnO}_2$  materials and was used for fabrication of lithium cell. Goswami et al. (2012) have synthesized cylindrical shaped CuO nanoparticles by thermal refluxing technique and used as an adsorbent for arsenic removal from water. They have mixed  $\text{CuCl}_2$ , NaOH and capping solvent with ethanol in a round bottom flask fitted with reflux condenser and heated the mixture for 16 h at  $75\text{ }^{\circ}\text{C}$ . Then, the dark precipitate obtained was centrifuged, washed and heated at  $110\text{ }^{\circ}\text{C}$  to form the nanoparticles. They have

observed that the prepared CuO followed Langmuir isotherm with an adsorption capacity of 1086.2  $\mu\text{g/g}$  for removal of arsenic from water. Sathyamoorthy et al. (2013) have synthesized MgO nanoflakes by thermal decomposition of precursors, which are prepared by a reflux condensation approach using ethylenediamine (EDA), hexamethyldiamine (HTMA) and triethanolamine (TEA) solvents separately. They have used the MgO nanoflakes for photocatalytic degradation of methyl orange (MO) dye and demonstrated that MgO nanoflakes possess appreciable photocatalytic activity for decomposing MO dye, when EDA is used as a capping agent. Zhong et al. (2006) have reported the synthesis of 3D flowerlike Iron oxides ( $\alpha\text{-Fe}_2\text{O}_3$ ,  $\gamma\text{-Fe}_2\text{O}_3$  and  $\text{Fe}_3\text{O}_4$ ) nanostructures (figure 2.14) by reflux condensation method. In a typical procedure, they have dissolved  $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ , urea, and tetrabutylammonium bromide (TBAB) in EG and the solution was refluxed at 195  $^\circ\text{C}$  for 30 min to form iron alkoxide precursor. Then the precursor was calcined at 450  $^\circ\text{C}$  in air for 3 h to form  $\alpha\text{-Fe}_2\text{O}_3$  and at 450  $^\circ\text{C}$  under  $\text{N}_2$  protection for 3 h to form  $\text{Fe}_3\text{O}_4$ . Then the resulting  $\text{Fe}_3\text{O}_4$  was calcined in air at 250  $^\circ\text{C}$  to form  $\gamma\text{-Fe}_2\text{O}_3$ . The obtained iron oxide nanomaterials were used as adsorbents for removal of As(V) and Cr(VI) from water and observed that the nanomaterials showed an excellent ability to remove heavy metal ions and other pollutants in water treatment. The maximum adsorption capacity of  $\alpha\text{-Fe}_2\text{O}_3$ ,  $\gamma\text{-Fe}_2\text{O}_3$  and  $\text{Fe}_3\text{O}_4$  were found to be 5.31, 4.75 and 4.65 mg/g, respectively for removal of As(V) and 4.47, 3.86 and 4.38 mg/g, respectively for removal of Cr(VI) from water.

**Figure 2.14** a) SEM and b) TEM images of the as-obtained  $\alpha\text{-Fe}_2\text{O}_3$ . c) High-magnification TEM image of the petal of the flowerlike structure of the as-obtained  $\alpha\text{-Fe}_2\text{O}_3$ . Inset: a high-resolution TEM (HRTEM) image taken from the as-obtained  $\alpha\text{-Fe}_2\text{O}_3$  nanoparticle. d) SAED pattern of the as-obtained  $\alpha\text{-Fe}_2\text{O}_3$ . e) SEM image of the as-obtained  $\text{Fe}_3\text{O}_4$ . f) SEM image of the as-obtained  $\gamma\text{-Fe}_2\text{O}_3$  (Zhong et al. 2006).

Similarly, Bharathi et al. (2010) have synthesized single-crystalline porous hematite nanorods with diameter  $\sim 20$  nm and length  $\sim 125$  nm by a low temperature reflux condensation method. In a typical experiment, precursor solution was prepared with  $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$  and  $(\text{NH}_2)_2\text{CO}$  and refluxed at a temperature slightly above the decomposition temperature of urea. Then the refluxing mixture was aged at  $90\text{--}95^\circ\text{C}$  for 12 h to form akagenite nanorods. Then the akagenite nanostructures were transformed to porous hematite nanostructures upon calcination at  $300^\circ\text{C}$  for 1 h. The prepared hematite nanorods showed excellent photocatalytic activity towards Rhodamine B from water.

### **2.3.2. Mixed metal oxide nanocomposites by Reflux method**

Mageshwari et al. (2015) reported the synthesis of novel  $\text{CuO--CuCr}_2\text{O}_4$  nanocomposite photocatalysts by reflux condensation method and evaluated their photocatalytic activity by monitoring the photodegradation of methyl orange (MO) and methylene blue dyes (MB) under UV light irradiation. In a typical synthesis,  $\text{Cu}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$  and  $\text{Cr}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$  was added in water to form a homogeneous blue color solution and refluxed at  $100^\circ\text{C}$  for 12 h to form cluster-like  $\text{CuO--CuCr}_2\text{O}_4$  nanocomposite microspheres. They have observed that, the  $\text{CuCr}_2\text{O}_4$  loaded CuO showed enhanced photocatalytic activity for MO and MB dyes, and followed pseudo-first-order kinetics. Li et al. (2015) have synthesized 3D flower-like iron(III) oxide–indium(III) oxide ( $\text{Fe}_2\text{O}_3\text{--In}_2\text{O}_3$ ) binary metal oxide nanocomposites by a simple and economical reflux method. In a typical synthesis procedure, they have refluxed a mixture solution of ferric chloride, indium nitrate, urea and tetrabutylammonium bromide in ethylene glycol at  $220^\circ\text{C}$  for 4h followed by calcination at  $450^\circ\text{C}$  for 3 h to form the  $\text{Fe}_2\text{O}_3\text{--In}_2\text{O}_3$  nanocomposite. Shafiu et al. (2014) have reported the synthesis of  $\text{Co}_3\text{O}_4@\text{ZnO}$  nanocomposite by a two-step reflux method using pre-prepared  $\text{Co}_3\text{O}_4$  nanoparticles. They have taken  $\text{Co}(\text{acac})_3$  and TEG in a three-neck round-bottomed flask equipped with a condenser with continuous stirring under argon. Then the mixture was refluxed at  $280^\circ\text{C}$  for 45 min to form colloidal suspension containing  $\text{Co}_3\text{O}_4$  nanoparticles. Then zinc acetate was added into the colloidal suspension obtained and the mixture was refluxed again at  $270^\circ\text{C}$  for additional 45 min to form colloidal suspension containing  $\text{Co}_3\text{O}_4@\text{ZnO}$  nanocomposites. Then the products obtained were washed and dried at  $300^\circ\text{C}$  for 3 h to form  $\text{Co}_3\text{O}_4@\text{ZnO}$  nanocomposites with average particle diameter 46 nm (figure 2.15). Mageshwari et al. (2015) have synthesized nanostructured  $\text{CuO--ZnO}$  nanocomposites taking different concentrations of  $\text{Zn}^{2+}$  (5%, 10%, 15%, 20% and 25%,) by reflux condensation method without using any surfactant and have studied their photocatalytic activity for methyl orange and methylene

blue dyes under UV light irradiation. They have prepared an aqueous solution of  $\text{Cu}(\text{NO}_3)_3 \cdot 3\text{H}_2\text{O}$  and  $\text{Zn}(\text{CH}_3\text{COO})_2 \cdot 2\text{H}_2\text{O}$  and injected  $\text{NH}_4\text{OH}$  solution to the above suspension. Then the mixture solution was refluxed at  $100^\circ\text{C}$  for 12 h to form CuO–ZnO nanocomposites. They have observed that pure CuO contains 3D flower-like hierarchical architecture while CuO–ZnO nanocomposites contains flower-like CuO microspheres decorated with rod-like ZnO particles (figure 2.16). They have reported that photodegradation activity of CuO–ZnO nanocomposites increased with  $\text{Zn}^{2+}$  concentration due to the reduced recombination and efficient separation of photogenerated charge carriers.

**Figure 2.15** TEM micrographs of  $\text{Co}_3\text{O}_4@\text{ZnO}$  nanocomposite together with its particle size distribution diagram (Shafiu et al., 2014)

**Figure 2.16** FESEM and TEM (scale bar is 0.21  $\mu\text{m}$ ) images (a) and (b) pure CuO, (c) and (d) CuO-5% ZnO, (e) and (f) CuO-10% ZnO, (g) and (h) CuO-25% ZnO (Mageshwari et al. 2015).

## 2.4. Characterization Techniques

There are numerous analytical techniques used for characterizing metal oxide nanomaterials and mixed metal oxide nanocomposites. Here, we have deliberated the basic principles of few techniques that have been used in the experimental part of this research work. The various techniques included are X-ray Diffraction (XRD), Scanning electron microscopy (SEM), Transmission electron microscopy (TEM), absorption spectroscopy (UV-Vis), Infrared spectroscopy (FT-IR), Brunauer-Emmet-Teller (BET) surface area and X-ray photoelectron Spectroscopy (XPS).

### 2.4.1. X-ray diffraction

X-ray diffraction (XRD) is an essential structural technique for characterization of nanocrystalline materials. The main objective of this technique is to determine structural phase and crystallite size of nanomaterials. Diffraction patterns of the nanomaterials are recorded with a X-ray diffractometer using Cu K $\alpha$  radiation ( $\lambda = 1.5418 \text{ \AA}$ ). By investigative diffraction pattern, one can identify the crystalline phase of nanomaterial. X-Ray Diffraction is in accordance with the principle of Bragg's law:

$$n\lambda = 2d\sin\theta \quad (2.1)$$

here,  $d$  is interplaner distance between lattice planes of miller indices,  $\lambda$  is the wavelength of the incident X-ray and  $\theta$  is Bragg angle. The widths of the diffraction peaks are closely related to the size, size distribution, defects and strain in the nanocrystals. For nanomaterials, as the size of the nanocrystals decreases, the peak width is broadened due to loss of long range order relative to bulk. The crystallite size of nanomaterials can be estimated from the peak width of the diffraction pattern corresponding to a particular (hkl) reflection plane using the Debye-Scherrer formula:

$$D = \frac{0.9\lambda}{\beta\cos\theta} \quad (2.2)$$

here,  $D$  is the mean crystallite size, which may be smaller or equal to the grain size,  $\lambda$  is the wavelength of the incident X-ray,  $\theta$  is Bragg angle and  $\beta$  is the full width half at maximum (FWHM) of the peaks in radians.

Formation of  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  (JCPDS: 72-1305) precursors and their conversion to  $\alpha\text{-Fe}_2\text{O}_3$  (rhombohedral phase, JCPDS: 33-0664) and  $\text{Fe}_3\text{O}_4$  (cubic phase, JCPDS: 65-3107) during the annealing processes under different atmosphere was clearly demonstrated by XRD (Du et al.

2010). With increase in increasing calcination temperature from 700 to 800 °C, the increase in the peak intensity and hence improvement of crystallization of anatase and rutile phases of TiO<sub>2</sub> were clearly explained using XRD by Xiao et al. (2010). Phase identification of three different phases of face-centered cubic Ag (JCPDS No. 04-0783), cubic magnetite (JCPDS No. 36-1451) and cubic ZnFe<sub>2</sub>O<sub>4</sub> (JCPDS No. 22-1012) of a mesoporous carbon fibers containing ternary nanocomposite ZnFe<sub>2</sub>O<sub>4</sub>/Fe<sub>3</sub>O<sub>4</sub>/Ag was done by XRD (Xie et al., 2012).

#### **2.4.2. Scanning electron microscopy (SEM)**

Scanning electron microscopy (SEM) is a powerful and popular technique for imaging surface of a sample and detecting signals from the interaction of the incident electron with the sample surface. When incident electron beams interact with specimen surface, secondary electrons with energies typically smaller than 50 eV evolve from the surface. The emission efficiency of the secondary electron depends upon the surface geometry, surface chemical characteristics and bulk chemical composition. Thus SEM can provide information about the surface topology, morphology and chemical composition. The high resolution capability of SEM makes it useful for characterization of nanomaterials.

The shape and morphology of nanostructured materials can be preliminary determined by SEM. The rod shaped morphology of prepared  $\alpha$ -FeOOH and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanomaterials with diameter about 30 nm and length up to 400 nm was determined by Zeng et al. (2007) using FESEM. Deng et al. (2014) have described the growth of the CuO nanocubes (with diameters ranging from 40 nm to 80 nm) onto the TiO<sub>2</sub> nanofibers (with diameters of about 200 nm) surface to form hierarchical heterostructures using FESEM (Deng et al., 2014).

#### **2.4.3. Transmission electron microscopy (TEM)**

Transmission electron microscopy (TEM) is a high spatial resolution structural and chemical characterization instrument. An advanced TEM has capability to directly image atoms in crystalline specimens at resolution close to 0.1 nm, which is smaller than interatomic distance. An electron beam can also be focused to a diameter smaller than 0.3 nm, by which quantitative chemical analysis from a single crystal is possible. TEM can be used to characterize metal oxide nanomaterials to determine particle size, shape, crystallinity and interparticle interaction (Zhang, 2009).

Meng et al. (2010) have investigated the shape, size and morphology of uniform coalescent moniliforme-shape  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> straight nanochains built up of single crystal building blocks using TEM and found that the one-dimensional coalescent architectures were built up of

single crystal building blocks with an average diameter of 19.8 nm. Starfish-shaped hollow structures of  $\text{Co}_3\text{O}_4/\text{ZnFe}_2\text{O}_4$  nanocomposite were investigated using TEM. It has been observed that the nanotubes of the starfish-shaped materials are highly porous, consisting of numerous  $\text{ZnFe}_2\text{O}_4$  nanocrystals of 10 nm (Hu et al., 2015).

#### 2.4.4. UV-Vis spectroscopy

UV-visible spectroscopy is one of the simplest and useful optical characterization techniques for studying optical and electronic properties of nanomaterials. Measurement of light absorption due to electronic transitions in nanomaterials is the basic operating principles of the spectroscopic technique. The wavelength of light required for electronic transition is typically in the UV and visible region of the electromagnetic spectrum, hence electronic spectroscopy is called UV-visible spectroscopy.

The UV-vis spectrometer records the intensity of absorption (A) as a function of wavelength. Let  $I_0$  and  $I_t$  are the intensities of incident and transmitted rays of light, respectively. Then, based upon Beer's law, the absorbance is related as:

$$A = \log \frac{I_0}{I_t} \quad (2.3)$$

$$\text{or,} \quad A = \epsilon c x \quad (2.4)$$

here,  $x$ =sample path length,  $c$ =concentration and  $\epsilon$ =molar extinction coefficient ( $\text{mol}^{-1}\text{cm}^{-1}$ ).

This characterization technique provides the preliminary concept of particle size, size distribution such as mono or polydispersity and band-gap of semiconductor metal oxide nanomaterials. Saha and Bhunia (2013) have studied the optical and electronic properties of  $\text{Fe}_2\text{O}_3$  nanoparticles using UV-vis spectroscopy and calculated the band-gap from it. Xia et al. (2008) have measured the UV-Vis diffuse reflectance spectra of  $\text{Fe}_2\text{O}_3/\text{SnO}_2$  nanocomposite photocatalyst for the determination of the shifting of absorption edges of the samples and also calculated the band-gap using this characterization.

#### 2.4.5. Fourier transforms infrared spectroscopy (FT-IR)

Infrared is a common vibrational spectroscopy technique useful for characterizing structural properties such as vibrational frequencies of molecules and phonons for determination of functional groups of the sample.

IR spectroscopy is based on measurement of transmitted IR light through a sample. For molecules, the IR spectrum reflects their vibrational modes, determined by selection rule. For nanoparticles, IR spectrum measures the phonon mode with appropriate selection rules that

are determined by their crystal symmetry properties. Interaction between the surface molecules or ions with nanoparticles usually cause change in the vibrational or phonon frequencies. Hence the changes in frequencies measured in IR spectrum can give information about the interaction between the nanoparticles and surface molecules. Nowadays researchers are using various commercial spectrometer including FTIR (Fourier transform IR) (Zhang, 2009).

FTIR spectroscopy has been applied to determine the broad band centered -OH groups ( $3430\text{ cm}^{-1}$ ), characteristic absorption peak of Fe-O ( $735\text{ cm}^{-1}$ ) and characteristics absorption peak of Zn-O ( $548\text{ cm}^{-1}$ ) of  $\text{ZnFe}_2\text{O}_4$  nanoparticles (Habibi and Habibi, 2013). Umare and Shambharkar (2012) used FTIR spectroscopy to determine characteristic absorption at  $474$  and  $578\text{ cm}^{-1}$  correspond to the Fe-O vibrations in  $\alpha\text{-Fe}_2\text{O}_3$  and C=C stretching modes of benzenoid and quinoid ring ( $1504$  and  $1585\text{ cm}^{-1}$ ), C-H deformation of aromatic rings ( $826\text{ cm}^{-1}$ ), C-N stretching of secondary aromatic amine ( $1154\text{ cm}^{-1}$ ), C-N $^{\bullet+}$  stretching vibration in protonic acid doped PANI from SDBS-PANI ( $1307\text{ cm}^{-1}$ ) and  $\text{SO}_3\text{H}$  of SDBS ( $513\text{ cm}^{-1}$ ) of Polyaniline (PANI)- $\alpha\text{-Fe}_2\text{O}_3$  nanocomposites.

#### **2.4.6. Brunauer-Emmett-Teller (BET) surface area**

The specific surface area of nanoparticle powder is determined by physical adsorption of  $\text{N}_2$  gas on the surface of the solid and by calculating the amount of adsorbate gas corresponding to monolayer coverage on the nanomaterials surface. The determination is typically carried out at liquid nitrogen temperature. The amount of  $\text{N}_2$  gas adsorbed on the nanomaterials surface can be measured by a volumetric or continuous flow procedure.

Using BET surface area analytical technique, determination of surface area, pore volume, pore diameter, pore size distribution and pore density measurements is carried out. Using this technique, Zhang et al. (2013) have measured  $\text{N}_2$  adsorption-desorption isotherms and pore size distribution (PSD) of  $\alpha\text{-Fe}_2\text{O}_3$  nanoparticles. They have observed that the nanoparticles are mesoporous nature, due to appearance of a distinct type IV hysteresis loop in the range of  $0.5$  to  $1.0\text{ P/P}_0$  and from PSD curve, the calculated the mesopores diameter about  $3$  and  $20\text{ nm}$ . The surface area of the  $\alpha\text{-Fe}_2\text{O}_3$  nanoparticles was found to be  $112\text{ m}^2\text{ g}^{-1}$ . The BET surface area, pore diameter and mesoporous structure of Cr-MCM-41 and Al, Cr-MCM-41 catalyst have been measured by Lezanska et al. (2007). According to them the BET surface area of  $3\%\text{Cr-MCM-41}$ ,  $5\%\text{Cr-MCM-41}$ ,  $6\%\text{Cr-MCM-41}$  and  $0.7\%\text{Cr}+2.9\%\text{Al-MCM-41}$

were found to be 1117, 1043, 1110 and 557 m<sup>2</sup>/g, respectively and the pore diameters were found to be 1.7, 2.8, 3.1 and 4.3 nm, respectively.

#### **2.4.7. X-ray photoelectron spectroscopy (XPS)**

The XPS technique is essentially used for elemental surface chemical analysis. Hence, the technique is also known as ESCA. XPS is based on the principle of measurement of the kinetic energy of photoelectrons generated when sample is illuminated with soft X-ray radiation in the ultrahigh vacuum. The principle follows the equation based on total energy conversion:

$$h\nu + E_i = KE + E_f \quad (2.5)$$

here, one X-ray photon with energy  $h\nu$  is used to excite an atom in its initial state with energy  $E_i$  and to eject an electron with kinetic energy,  $KE$ , with an atom resulting in final state of energy  $E_f$  (Zhang, 2009). The energy of the photoelectrons thus leaving the sample is determined and this gives a spectrum of intensity as a function of binding energy. The binding energies of the peaks are characteristics of each element. Hence, XPS can also provide chemical binding information.

Xia et al. (2013) have determined C-C, C-OH and C(O)O groups of graphene plane, Sn 3d<sub>3/2</sub> (486.9 eV), Sn 3d<sub>5/2</sub> (495.4 eV), Fe 2p<sub>3/2</sub> (712.2 eV) and Fe 2p<sub>1/2</sub> (725.6 eV) peaks in Graphene/Fe<sub>2</sub>O<sub>3</sub>/SnO<sub>2</sub> ternary nanocomposites using XPS. Similarly, Zhang et al. (2012) have shown Ti, Ag, O, and C elements with sharp photoelectron peaks at binding energies of 530 eV (O1s), 459 eV (Ti2p), 368 eV (Ag3d), and 285 eV (C1s) in Ag Cluster-Doped TiO<sub>2</sub> nanoparticles using XPS. They have also evaluated the element ratio of Ag to Ti as 0.87% using high-resolution spectra of Ti2p and Ag3d.

## **2.5. Concluding remarks**

Metal oxide nanocomposites are extremely attractive since they exhibit surface bifunctional properties. In the nanosized regime, specific metal oxide interactions can indeed be responsible for the enhanced physicochemical properties. Coupling of one metal oxide with other has also been observed to increase the adsorption & photocatalytic performance. In this chapter, we have reviewed various literatures report on the preparation and environmental applications of different iron oxides and iron oxide based composite nanomaterials. A large number of literatures are available on the synthesis and environmental applications of Fe<sub>2</sub>O<sub>3</sub>, SnO<sub>2</sub>, CuO, MgO, and ZnO nanomaterials. Fe<sub>2</sub>O<sub>3</sub> is found to very important adsorbent and

photocatalyst for decontamination of both organic and inorganic pollutants from aqueous media. There are also various literatures available on other metal oxides such as  $\text{SnO}_2$ ,  $\text{MgO}$ ,  $\text{CuO}$  and  $\text{ZnO}$  nanomaterials that have been used as adsorbents and photocatalysts. More recently, various groups have focussed their research on the synthesis of metal oxide hybrid or composite nanomaterials in order to further improve the performance of individual metal oxide nanomaterials. Metal oxide nanocomposites are observed to be showing enhanced photocatalytic as well as surface adsorption properties and hence have been used for environmental applications. A large number of reports are available on environmental applications of iron oxide base polymer, graphene and graphene oxide nanocomposite materials. However, a very few reports are available on synthesis of  $\text{Fe}_2\text{O}_3$  based metal oxide nanocomposites such as  $\text{Fe}_2\text{O}_3/\text{SnO}_2$ ,  $\text{Fe}_2\text{O}_3/\text{MgO}$ ,  $\text{Fe}_2\text{O}_3/\text{CuO}$  and  $\text{Fe}_2\text{O}_3/\text{ZnO}$ . So, in order to carry out extensive studies on the synthesis, structural properties and crystalline phases as well as their applications towards adsorptive removal and photocatalytic degradation of organic dyes pollutants, we have studied the synthesis and application of  $\text{Fe}_2\text{O}_3$  based  $\text{SnO}_2$ ,  $\text{MgO}$ ,  $\text{CuO}$  and  $\text{ZnO}$  nanocomposites for decontamination of organic dyes from aqueous media.

Four different organic dyes (Congo red, Methylene blue, Malachite green and Methyl orange) have been chosen as model organic pollutants to study the adsorptive removal and photocatalytic degradation performance of the prepared iron oxides and their nanocomposites. Among the four dyes two anionic and two cationic dyes have been chosen with different structure and functionality. Congo red and Methyl orange are anionic and azo dyes. Similarly, Methylene blue and Malachite green are cationic dyes. Congo red [1-naphthalene sulfonic acid, 3, 3'-bis(4, 4'-biphenylenebis (azo)) bis (4-amino-) disodium salt, CR] is a benzidine-based anionic diazo dye, i.e. a dye with two azo groups. It is toxic to many organisms and is a suspected carcinogen and mutagen. The dye has been known to cause an allergic reaction and to be metabolised to benzidine, a human carcinogen (Afkhami and Moosavi, 2010). Methylene blue [3,7-bis(Dimethylamino)-phenothiazin-5-ium chloride, MB] have various harmful effects such as nausea, abdominal and precordial pain, dizziness, headache, profuse sweating, hemolytic anemia, hyperbilirubinemia, acute renal failure and mental confusion. Contact with methylene blue may also cause photoirritant contact dermatitis (PICD). Methyl Orange [Sodium 4-[(4-dimethylamino) phenyldiazenyl] benzenesulfonate, MO] is an azo dye used in textile industries and is an orange-coloured anionic dye. Methyl Orange is a harmful compound that exists in textile waste waters and has

various harmful effects on human beings. For example, it may cause eye or skin irritation, or inhalation may cause gastrointestinal irritation with nausea, vomiting, and diarrhea (Azami et al., 2012). Malachite green [4-{{[4-(dimethylamino) phenyl] (phenyl) methylenidene}-N, N-dimethylcyclohexa-2, 5-dien-1-iminium chloride, MG] also called Basic Green 4 is the most widely used dye for colouring purpose among all other dyes of its category. It is highly cytotoxic and carcinogenic to mammalian cells and acts as a liver tumor promoter. It decreases food intake capacity, growth and fertility rates; causes damage to liver, spleen, kidney and heart; inflicts lesions on skin, eyes, lungs and bones. MG is also environmentally persistent and acutely toxic to a wide range of aquatic and terrestrial animals (Saha et al., 2010). The functional groups present in organic molecule also play an important role in adsorption as well as the photocatalytic studies. So in order to study a wide range of applications of our synthesized nanocomposite materials we have selected the four different dyes having different charges, different functional groups as model organic pollutants in this thesis.

## 2.6. Research Objectives

The main objectives of this research work are as follows:

- To synthesize novel metal oxide nanomaterials especially iron oxides, iron oxide based nanocomposites such as  $\text{Fe}_2\text{O}_3/\text{SnO}_2$ ,  $\text{Fe}_2\text{O}_3/\text{CuO}$ ,  $\text{Fe}_2\text{O}_3/\text{ZnO}$  and  $\text{Fe}_2\text{O}_3/\text{MgO}$  nanocomposites and iron oxide impregnated mesoporous MCM-41 using facile low cost wet chemical synthetic methods.
- To study the formation, stability, existence of crystalline phases, porous structures and surface properties of the prepared metal oxide nanomaterials using different sorptometric, scattering, spectroscopic and microscopic analytical techniques.
- Environmental applications of the nanomaterials towards surface adsorption and photocatalytic degradation of organic dyes from aqueous media.
- To study the adsorption and photocatalysis efficacy of the prepared metal oxide nanomaterials for a wide range of toxic organic dyes having different charge, functionality and molecular size.
- Fundamental understanding and correlation of the surface properties of the material with their activity.

## CHAPTER-3

### ONE DIMENSIONAL (1D) IRON OXIDES AND IRON-TIN MIXED OXIDE NANOCOMPOSITES: SYNTHESIS AND SORPTION STUDIES

#### PART A: IRON OXIDE ( $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ , $\gamma\text{-Fe}_2\text{O}_3$ AND $\alpha\text{-Fe}_2\text{O}_3$ ) NANORODS

##### 3.1. Introduction

Water pollution is a major global problem which is the leading worldwide cause of deaths and diseases. Many synthetic chemicals are extremely resistant to biodegradation by native microorganisms and are major water pollutants, such as pesticides, organochlorines, polychlorinated biphenyls, polycyclic aromatic hydrocarbons, wood preservatives, synthetic polymers and synthetic dyes. Synthetic dyes are extensively used in different industries, including paper, plastic, leather, pharmaceutical, food, cosmetic, dyestuff, and textile industries (Ge et al., 2012; Haider et al., 2011). Dyeing is a fundamental operation during the textile fiber processing. This operation causes the production of colored waste waters, depending on the degree of fixation of the dyes on the substrates, which varies with the nature of the substances, the desired intensity of coloration, and the application method (Wawrzekiewicz, 2012). According to a recent study, approximately 700,000 tons of different dyes are produced annually in the world, and more than 60 % of the world dye production is consumed by textile industries (Hu et al., 2010). Due to the presence of hazardous wastes and toxic pollutants in the effluents from the textile industry, they are highly problematic to environment. Among them, organic dyes are one of the major groups of pollutants in waste waters. These toxic dyes have significant impact on the human health and the aquatic life. The used dyes may cause an eco-toxic hazard and induce the potential danger of bioaccumulation (Toor and Jin, 2012; Wang et al., 2012; Kumar and Bansal, 2012).

The toxic nature of dye is that on decomposition it gives hazardous products such as Carbon dioxide, carbon monoxide, nitrogen oxide and hydrogen chloride. These products are toxic and causes severe health problem to living beings (Irama et al., 2010). Congo Red [1-naphthalene sulfonic acid, 3, 30-(4, 40-biphenylenebis(azo))bis(4-amino-)disodium salt] an anionic dye has been known to cause an allergic reaction and to be metabolised to benzidine, a human carcinogen. Congo red mainly occurs in the effluents discharged from textile, paper,

printing, leather industries, etc. Its molecular formula is  $C_{32}H_{22}N_6Na_2O_6S_2$  (Yosef and Avnir, 2011; Chatterjee et al., 2010).

There are several methods for removal of organic dyes from aqueous solution such as: coagulation (Marechal et al., 1997), nanofiltration (Chakraborty et al., 2003), ozonation (Khadhraoui et al., 2009), ultrasound irradiation (Song et al., 2009), ion exchange (Wawrzkievicz and Hubicki, 2010), activated carbon filter (Chan et al., 2009), oxidation (Lucas and Peres, 2006), membrane processes (Sachdeva and Kumar, 2009), micellar enhanced ultrafiltration (Purkait et al., 2004), adsorption (Wang et al., 2012) etc. Among all the processes, adsorption is a very effective separation technique. Now it is considered as superior to other techniques for water treatment in terms of effectiveness, initial cost, simplicity of design, and ease of operation. Similarly, this technique can handle fairly large flow rates, producing a high-quality effluent that does not result in the formation of harmful substances, such as ozone and free radicals. In this process the dye species are transferred from the water effluent to a solid phase that leads to decrease the effluent volume (Dawood and Sen, 2012; Toor and Jin, 2012; Wang et al., 2012; Zhu et al., 2012).

Many researchers used various adsorbents for removal of Congo red from aqueous solution such as: fly ash (Dizge et al., 2008), bentonite (Lian et al., 2009), montmorillonite (Wang and Wang, 2008), chitosan (Chatterjee et al., 2009), organo-attapulgite (Chen and Zhao, 2009), activated carbon (Lorenc-Grabowska and Gryglewicz, 2007; Namasivayam and Kavitha, 2002; Purkait et al., 2007), bottom ash and deoiled soya (Mittal et al., 2009), *Azadirachta indica* leaf powder (Bhattacharyya and Sharma, 2004), *Trametes versicolor* (Binupriya et al., 2008), jute stick powder (Panda et al., 2009), *Aspergillus niger* (Fu and Viraraghavan, 2002), cattail root (Hu et al., 2010), anilinepropylsilica xerogel (Pavan et al., 2008), perlite (Vijayakumar et al., 2009), sawdust (Jain and Sikarwar, 2008), rice husk ash (Chowdhury et al., 2009), mesoporous hematite ( $\alpha\text{-Fe}_2\text{O}_3$ ) (Yu et al., 2008), CNTs/ $\beta\text{-FeOOH}$  (Song et al., 2012) etc. However, some of these adsorbents do not have good adsorption capacities for anionic dyes. Nowadays, research focused on the use of nanotechnology for environmental clean-up/remediation. Arising out of their ultrafine size, large surface area & interface dominated properties nano-sized materials can be used to decontaminate the toxic organic and inorganic chemical from the environments. Recently, Afkhami and Moosavi (2010) used maghemite nanoparticle, prepared by co-precipitation method, for removal of Congo red from aqueous solution.

From the literature review we observed that iron oxide is an efficient adsorbent for removal of both organic and inorganic pollutant from the aqueous stream and is also a non toxic metal oxide. This oxide is easily prepared using both basic and acidic medium. Our objective is to prepare iron oxide based nanocomposite materials for environmental applications prior to this we have synthesized iron oxide nanomaterials via iron oxalate precipitation method at room temperature. The low temperature calcination product of iron oxalate leads to form different iron oxide nanomaterials. Therefore for the convenient, low cost a, easy preparation and to adopt environmental benign condition we have chosen the oxalate precipitation method for synthesis of iron oxide nanomaterials (Borel et al., 2014). In the present investigation, by using a modified wet chemical method, we have prepared different 1-dimensional nano-adsorbents such as: Ferrous oxalate ( $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ ) nanorod, hematite ( $\alpha\text{-Fe}_2\text{O}_3$ ) nanorod and maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ) nanorod. The prepared adsorbents were employed for removal of Congo red (CR) and a comparative study were carried out by evaluating equilibrium isotherms and kinetic data for selection of the most effective adsorbent among them.

## **3.2. Materials and Methods**

### **3.2.1 Materials**

Congo Red (CR, molecular formula  $\text{C}_{32}\text{H}_{22}\text{N}_6\text{Na}_2\text{O}_6\text{S}_2$ , molecular weight  $696.66 \text{ g mol}^{-1}$ ,  $\lambda_{\text{max}} = 498 \text{ nm}$ ), an anionic azo dye, obtained from Merck (India) was selected as dye. All chemicals used in the investigation such as: Ferrous sulphate heptahydrate, Oxalic acid dihydrate, CTAB and Ethanol were of analytical grade and were used without further purification. The chemicals were obtained from Merck (India).

### **3.2.2. Synthesis of Adsorbent**

Ferrous sulphate heptahydrate ( $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ ) was dissolved in 10 ml of double distilled water with intensive stirring to form solution-A. Oxalic acid dihydrate ( $\text{H}_2\text{C}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ ) and CTAB (Cetyl trimethylammonium bromide) were dissolved in 25 ml of ethanol with intensive stirring to form solution-B. Then solution-A was added to solution-B with intensive stirring to form a yellow coloured homogeneous solution. After addition the stirring was carried out for another 5 hours. Then the yellow coloured precipitate obtained was centrifuged, washed thoroughly by ethanol and double distilled water and dried at  $80^\circ\text{C}$  for 2 hours to form  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  nanorod. A part of this nanopowder was heated at  $300^\circ\text{C}$  in moist condition to obtained  $\gamma\text{-Fe}_2\text{O}_3$  nanorod and heated at  $550^\circ\text{C}$  to obtained  $\alpha\text{-Fe}_2\text{O}_3$  nanorod.

### 3.2.3. Characterization of Adsorbent

Various characterization techniques were used to characterize the 1-D nanoadsorbents. The crystalline phases were identified by mean of X-ray diffraction (XRD) by a PANalytical X-ray diffractometer with Cu K $\alpha$  radiation ( $\lambda$ ) 1.54156 °Å at a scan rate of 2°/min. The surface morphology of the prepared adsorbent materials was characterized by a JEOL JSM-5300 scanning electron microscope (SEM) operated at an acceleration voltage of 15 and 20.0 kV. The size of the particle and selected area electron diffraction (SAED) pattern of the dried  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> powder was observed using a high resolution transmission electron microscope (TEM) (JEM-2100 HRTEM, Make-JEOL, Japan) with an acceleration voltage of 200KV. Fourier transform infrared spectroscopy (FTIR) results were recorded using Perkin-Elmer FTIR (Spectrum RX-I) spectrophotometer. Specific surface area and pore size distribution (PSD) were determined by the Brunauer-Emmett-Teller (BET) and Barrett-Joyner-Halenda (BJH) methods, respectively by N<sub>2</sub> adsorption-desorption technique by automated surface area and porosity analyser (COULTER SA 3100 Series Surface Area and Pore Analyzers). Prior to the analysis, sample was degassed under a vacuum (1X10<sup>-5</sup> Torr) at 150 °C for 1.5 h.

### 3.2.4. Adsorption Experiment

For the removal of Congo red (CR) dye from water, the adsorption experiments were carried out using the three prepared adsorbents: FeC<sub>2</sub>O<sub>4</sub>.2H<sub>2</sub>O,  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanorods. A stock solution of CR (1 g L<sup>-1</sup>) was prepared in double distilled water and desired concentrations of the dye were obtained by diluting the same with double distilled water. The calibration curve of CR was prepared by measuring the absorbance of different concentrations of the samples at maximum absorbance at wavelength,  $\lambda_{\text{max}} = 498$  nm using UV-vis spectrophotometer. The amount of adsorption  $q_e$  is calculated by equation (Nethaji et al., 2012; Kumar et al., 2012):

$$q_e = \frac{C_0 - C_e}{w} V \quad (3.1)$$

where  $q_e$  is the amount of adsorption at equilibrium in mg g<sup>-1</sup>,  $C_0$  &  $C_e$  are the initial and equilibrium concentration of the dye in mg L<sup>-1</sup>,  $V$  is the volume of the dye solution taken in litre and  $w$  is the weight of the nanorod (adsorbent) in gram. All the adsorption experiments were carried out three times in replicates and the mean data obtained were taken in results and discussion section.

### 3.3. Results and Discussion

#### 3.3.1. Surface morphology

Figure 3.1 shows the SEM micrographs of as synthesised  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  nanorod,  $\gamma\text{-Fe}_2\text{O}_3$  nanorod and  $\alpha\text{-Fe}_2\text{O}_3$  nanorod. Figure 3.1a SEM micrograph suggests that the obtained  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  nanostructure exhibits the morphology of the nanorod with the diameter of about 100-200 nm and the length up to micrometres. Moreover, the surface of the  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  nanorods seems to be smooth, and no defects can be observed. When the  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  nanorods were annealed in air at 300 °C in moist condition,  $\gamma\text{-Fe}_2\text{O}_3$  nanorods were formed. Figure 3.1b shows the SEM, image of the as-synthesized  $\gamma\text{-Fe}_2\text{O}_3$  nanorods. It can be seen that the as-synthesized  $\gamma\text{-Fe}_2\text{O}_3$  nanorods retain the morphology of the  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  nanorods. Similarly when, the  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  nanorods were annealed in air at 550 °C,  $\alpha\text{-Fe}_2\text{O}_3$  nanorods were formed. Figure 3.1c shows the SEM, image of the as-synthesized  $\alpha\text{-Fe}_2\text{O}_3$  nanorods. It can also be seen that the as-synthesized  $\alpha\text{-Fe}_2\text{O}_3$  nanorods retain the morphology of the  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  nanorods. Figure 3.1d shows the EDX analysis of as-synthesized  $\gamma\text{-Fe}_2\text{O}_3$  nanorods, which confirms the presence of Fe and O elements.

**Figure 3.1** SEM micrographs of a)  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  nanorod, b)  $\gamma\text{-Fe}_2\text{O}_3$  nanorod, c)  $\alpha\text{-Fe}_2\text{O}_3$  and d) EDX of  $\gamma\text{-Fe}_2\text{O}_3$  nanorod.

A typical profile of TEM images of  $\gamma\text{-Fe}_2\text{O}_3$  are shown in Figure 3.2a and 3.2b, which gives further evidence of the formation of high yield aligned nanorods. A typical TEM image of a single  $\gamma\text{-Fe}_2\text{O}_3$  nanorod is given in figure 3.2c, which gives the average diameter of the rod is around 100 nm. The SAED pattern, taken from the same single nanorod (given in figure 3.2d), shows sharp bright rings which indicate the formation of polycrystalline spinel structure.

**Figure 3.2** (a, b and c) TEM images and (d) SAED pattern of  $\gamma\text{-Fe}_2\text{O}_3$  nanorod.

### 3.3.2. X-Ray diffraction analysis

The formation and phase analysis of the prepared nanomaterials were studied by XRD using Cu K $\alpha$  radiation. Figure 3.3 shows the XRD patterns of as synthesized  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  nanorod,  $\gamma\text{-Fe}_2\text{O}_3$  nanorod and  $\alpha\text{-Fe}_2\text{O}_3$  nanorod. Figure 3.3a represents the XRD pattern of  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  and contains the characteristics peaks and can be index to orthorhombic crystal structure according to JCPDS No: 22-0635. Figure 3.3b contains the characteristics peaks of  $\gamma\text{-Fe}_2\text{O}_3$  and can be index to cubic crystal structure according to JCPDS No: 39-1346. The XRD pattern of figure 3.3c represents the characteristics peaks of  $\alpha\text{-Fe}_2\text{O}_3$  and can be index

to rhombohedral crystal structure according to JCPDS No: 79-0007. The X-ray diffractograms reveal the crystalline nature of the compounds. The broadening of the peaks also indicates the decrease in the diameter and an increase in the surface to volume ratio of the compounds.

**Figure 3.3** XRD patterns of a)  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  nanorod, b)  $\gamma\text{-Fe}_2\text{O}_3$  nanorod and c)  $\alpha\text{-Fe}_2\text{O}_3$  nanorod.

Crystallite size and the lattice strain of the prepared samples are calculated from the X-ray diffractograms, by using the well-known Scherrer formula as follows:

$$L = \frac{K\lambda}{\beta \cos\theta} \quad (3.2)$$

Where  $L$  is average crystalline size,  $\lambda$  is the X-ray wavelength,  $\theta$  is the diffraction angle,  $\beta$  is the line broadening at half the maximum intensity (FWHM) in radians resulting from small crystallite size, and  $K$  is a constant approximately equal to unity and related to crystallite shape. The crystallite size and lattice strain of ferrous oxalate was found to be 22.6 nm and 1.196 %, respectively. When it was heated to 300 °C form  $\gamma\text{-Fe}_2\text{O}_3$  its crystallite size increased to 29.4 nm while lattice strain decreased to 0.5. Similarly, when the sample was further heated to higher temperature to form  $\alpha\text{-Fe}_2\text{O}_3$  its crystallite size still increases and lattice strain decreases. This phenomenon is also observed in the XRD patterns that for ferrous oxalate consists broadened peaks and  $\gamma\text{-Fe}_2\text{O}_3$  consists less broadened peaks while  $\alpha\text{-Fe}_2\text{O}_3$

Fe<sub>2</sub>O<sub>3</sub> contains comparatively sharp peaks. As the lattice strain of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> is least, it is the most stable form among the three samples. The unit-cell dimension of the synthesized samples was measured to determine the crystal structure and given in table 3.1.

**Table 3.1** Crystallographic information of the prepared nanorods.

Sample	Crystal Structure	Lattice Parameters (°Å)	Crystallite Size (nm)	Lattice Strain (%)
FeC <sub>2</sub> O <sub>4</sub> .2H <sub>2</sub> O	Orthorhombic	a=12.26, b=5.57, c=15.48	22.6	1.196
$\gamma$ -Fe <sub>2</sub> O <sub>3</sub>	Cubic	a=8.3515	29.4	0.5
$\alpha$ -Fe <sub>2</sub> O <sub>3</sub>	Rhombohedral	a=b=5.0285, c=13.736	39.1	0.433

### 3.3.3. FTIR study

To further confirm the formation and transformation from FeC<sub>2</sub>O<sub>4</sub>.2H<sub>2</sub>O to  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, FTIR analysis was performed. In figure 3.4a pattern, the peaks at 3358, 1631, 1315 and 496 cm<sup>-1</sup> are attributed to O-H, C=O, C-O and Fe-O functional groups, respectively, indicating the formation of FeC<sub>2</sub>O<sub>4</sub>.2H<sub>2</sub>O. In figure 3.4b pattern, the peak at 632 cm<sup>-1</sup> is due to Fe-O, which is characteristic peak of maghemite and at 1637 cm<sup>-1</sup> is due to presence of water of crystallisation in the sample. In figure 3.4c pattern, the peaks at 617 cm<sup>-1</sup> is due to longitudinal absorption (A<sub>u</sub>) and at 572 and 490 cm<sup>-1</sup> are due to transverse absorption (E<sub>u</sub>) of Fe-O vibrational mode of hematite.

**Figure 3.4** FTIR spectra of a) FeC<sub>2</sub>O<sub>4</sub>.2H<sub>2</sub>O nanorod, b)  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanorod and c)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorod.

### 3.3.4. N<sub>2</sub> Adsorption-Desorption Isotherm

The surface area and porosity nature of the prepared nanorods was carried out by N<sub>2</sub> adsorption-desorption isotherm technique. The adsorption-desorption isotherm and pore size

distribution are shown in figure 3.5. From figure 3.5a it is observed that, the BET and Langmuir surface areas of the prepared ferrous oxalate were found to be 27.550 and 24.945 m<sup>2</sup>/g. From figure 3.5b, the BET and Langmuir surface areas of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> were found to be 129.74 and 107.35 m<sup>2</sup>/g. Similarly, from figure 3.5c, the BET and Langmuir surface areas of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> were found to be 22.785 and 20.575 m<sup>2</sup>/g. From the above discussion it is observed that, the surface area of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> is highest among the prepared nanorods.

**Figure 3.5** BET isotherm and BJH isotherm (inset) of (a) Ferrous Oxalate, (b)  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>, and (c)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods.

### 3.3.5. Adsorption study of CR dye by different iron oxides

The different iron oxide nanorods such as:  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>,  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and FeC<sub>2</sub>O<sub>4</sub>.2H<sub>2</sub>O prepared by modified wet chemical method were used as adsorbents for removal of CR dye from aqueous solution. Adsorption studies were carried out by batch experiments using 50 ml of cleaned and dry glass bottle. Figure 3.6 shows the UV–Vis spectra of Congo red solutions of concentration 100 mg L<sup>-1</sup> before and after adsorption in the colloidal suspension of 0.05 g of different adsorbents, such as: FeC<sub>2</sub>O<sub>4</sub>.2H<sub>2</sub>O nanorod,  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanorod and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorod with reaction time 30 mins. At a  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> dosage of 0.05 g L<sup>-1</sup>, the colloidal suspension is

able to adsorb almost 100 % of Congo red (figure 3.6), and the photograph of before and after adsorption also confirm the removal of the Congo red at this dosage of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> (figure 3.6, inset).

**Figure 3.6** UV-Vis absorption spectra of a) initial Congo red with an initial concentration of 100 mg L<sup>-1</sup> and solutions (20 ml) after treated with 0.05 g of b) FeC<sub>2</sub>O<sub>4</sub>·2H<sub>2</sub>O, c)  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> and d)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> for 30 min.

#### 3.3.5.1. Effect of adsorbent dose

Adsorbent dosage is one of the most important parameter that has been considered to determine the optimum condition for the performance of adsorption. Essentially, insufficient dosage or overdosing would result in the poor performance in adsorption. Therefore, it is significant to determine the optimum dosage in order to minimize the dosing cost and sludge formation and also to obtain the optimum performance in treatment. The effect of adsorbent doses on the removal of CR using FeC<sub>2</sub>O<sub>4</sub>·2H<sub>2</sub>O,  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanorods was performed by mixing the nanorod samples of different weight to 20 ml of 100 mg/L CR, maintaining pH=7.6 (pH at normal condition) for 30 min contact time. The weight of the adsorbents was varied in the range 0.01-0.1 g. Figure 3.7a shows the UV-vis absorption spectra of CR solutions after being treated with different dosages of the prepared nanorod adsorbents using an initial dye concentration of 100 mg L<sup>-1</sup>. It is observed there is a continuous removal of CR with increase in adsorbent dose up to 0.05 g. This may be due to an increase in number of active sites of the adsorbent material with increasing amount of the adsorbent. Further increase in the amount of the adsorbent does not bring any considerable change in the adsorption i.e. approximately straight line is obtained. Therefore 0.05 g was chosen as the optimum amount for all studies of the adsorbents. The highest percentage of removal obtained for  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanorod among the three adsorbents.

### 3.3.5.2. Effect of contact time.

Time of contact of adsorbent and adsorbate plays an important role for adsorptive removal of organic dye from aqueous solution. It is helpful in understanding the amount of dye adsorbed at various time intervals by a fixed amount of the adsorbent. Figure 3.7b shows the adsorptive removal of Congo red with time variation by using  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ ,  $\alpha\text{-Fe}_2\text{O}_3$  and  $\gamma\text{-Fe}_2\text{O}_3$  nanorod adsorbents. In this section 0.05 g of each adsorbents were added into 20 ml of 100mg/L of CR solution maintaining pH=7.6, with varying time from 0 min to 60 min. From the figure, it is found that there is a consistent increase in percentage of removal up to 30 min and the adsorption equilibrium is attained after 30 min of contact time. This is due to the rate of adsorption decreased and a saturation stage was attained due to the accumulation of the adsorption sites by the dye ions. The highest removal of CR is found to be 97.97 % for  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ , 99.24 % for  $\gamma\text{-Fe}_2\text{O}_3$  and 84.62 % for  $\alpha\text{-Fe}_2\text{O}_3$  for 30 min contact time. Agitation time of 30 min was selected for further works.

**Figure 3.7** Effect of a) amount of adsorbent (dose), b) time, c) pH and d) Concentration on removal of Congo red by: ■)  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ , ●)  $\gamma\text{-Fe}_2\text{O}_3$  and ▲)  $\alpha\text{-Fe}_2\text{O}_3$  nanorods and e) Effect of initial dye concentration on adsorption capacity for the removal of Congo red.

#### *3.3.5.3. Effect of pH of CR solution*

Solution pH affects both aqueous chemistry and surface binding sites of the adsorbents. To investigate the effect of pH on the adsorption of CR dye the pH range 3–8 was chosen. The pH of the test solutions was adjusted by using HCl and NaOH solutions. 0.05 g of each adsorbents used in 20 ml of 100 mg/L CR solution of each pH value with 30 min agitation time. From figure 3.7c it is found that, for  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  and  $\gamma\text{-Fe}_2\text{O}_3$ , there is no significant change in the percentage adsorption by increasing pH from 3-6 and reached maximum at pH = 6 and then slightly decreased at higher pH in case of  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ . For  $\alpha\text{-Fe}_2\text{O}_3$ , the maximum percentage of removal occurs at pH = 5 and then decreases. This is due to for higher pH solution; the high negatively charged adsorbent surface sites did not favour the adsorption of deprotonated CR due to electrostatic repulsion (Afkhami and Moosavi, 2010).

#### *3.3.5.4. Effect of initial dye concentration on adsorption*

The initial concentration provides important information that overcomes the mass transfer resistance of all molecules between the aqueous and solid phases (Ghaedi et al., 2011). The adsorption is greatly influenced by the concentration of the solution, as the adsorptive reactions are directly proportional to the concentration of the solute (Mittal et al., 2009). In this section, 0.05 g of each adsorbent used each 20 ml of CR solution (natural pH) with concentration ranging from 50 mg/L to 300 mg/L and the agitation time was kept 30 min. It is found that with the increase in initial dye concentration, percentage adsorption decreases (figure 3.7d) while the equilibrium adsorption capacity of the adsorbent for CR increases with increasing initial dye concentration i.e. the more concentrated the dye solution, the higher the adsorption capacity (figure 3.7e). This is probably due to a high driving force for mass transfer in high dye concentration.

### **3.3.6. Adsorption Isotherm**

To determine equilibrium relationship of amount adsorbed by a unit weight of adsorbent ( $q_e$ ) with the concentration of adsorbent remaining in the medium at equilibrium ( $C_e$ ), studies of various adsorption isotherm models is required, which can optimise the design of a sorption system. There is various type of adsorption models developed such as: Freundlich, Langmuir, Tempkin, D–R isothermal models, etc (Mittal et al., 2009). The most common models such as Freundlich and Langmuir equations are used to investigation of this study. The initial dye concentrations were varied from 50 to 300 mg/L using 0.05 g of each adsorbent in 20 ml of CR solution (natural pH) with agitation time 30 min.

### *Langmuir isotherm*

The Langmuir isotherm model assumes monolayer coverage of adsorbate on a homogeneous adsorbent surface. This model does not consider surface heterogeneity of the sorbent. It assumes adsorption will take place only at specific site on the adsorbent (Chatterjee et al., 2009; Bayazit and Inci, 2013). The Langmuir equation is given as:

$$\frac{q_e a_L}{K_L} = \frac{K_L C_e}{(1 + K_L C_e)} \quad (3.3)$$

The linear form of the Langmuir isotherm is:

$$\frac{C_e}{q_e} = \frac{1}{K_L q_{max}} + C_e/q_{max} \quad (3.4)$$

where  $a_L$  ( $\text{Lmg}^{-1}$ ) and  $K_L$  ( $\text{Lg}^{-1}$ ) are the Langmuir constants,  $q_{max}(=K_L/a_L)$  is the maximum adsorption capacity corresponding to complete monolayer coverage ( $\text{mg g}^{-1}$ ), which depends upon the number of adsorption sites (Rahimi et al. 2011). The values of  $q_{max}$  and  $K_L$  are calculated from the slopes and intercepts of the straight lines of plot of  $C_e/q_e$  versus  $C_e$ .

### *Freundlich isotherm*

The Freundlich isotherm model is an empirical equation that describes the surface heterogeneity of the sorbent. It considers multilayer adsorption with a heterogeneous energetic distribution of active sites, accompanied by interactions between adsorbed molecules (Namasivayam and Kavitha, 2002). The Freundlich isotherm equation is given as (Inci et al., 2011):

$$q_e = K_F C_e^{1/n} \quad (3.5)$$

The linear form of the Freundlich isotherm is:

$$\ln q_e = \ln K_F + 1/n \ln C_e \quad (3.6)$$

where  $C_e$  is the equilibrium concentration ( $\text{mg L}^{-1}$ ),  $q_e$  is the amount adsorbed at equilibrium ( $\text{mg g}^{-1}$ ) and  $K_F$  and  $n$  are Freundlich constants, related to the extent of the adsorption and the degree of nonlinearity between solution concentration and adsorption, respectively.  $K_F$  and  $(1/n)$  can be determined from the linear plot of  $\ln q_e$  versus  $\ln C_e$ .

The essential characteristics of Langmuir isotherm can be expressed by a dimensionless constant called equilibrium parameter ( $R_L$ ) that is defined by the following equation (Chatterjee et al., 2009; Afkhami et al., 2010; Kumar et al., 2012):

$$R_L = \frac{1}{1 + a_L C_0} \quad (3.7)$$

where  $a_L$  and  $C_0$  are the parameters as defined previously. The value of  $R_L$  calculated from the above expression. The nature of the adsorption process to be either unfavourable ( $R_L > 1$ ),

linear ( $R_L = 1$ ), favourable ( $0 < R_L < 1$ ) or irreversible ( $R_L = 0$ ) (Lian et al., 2009). Here  $R_L$  values obtained are listed in table 3.2. The linear Langmuir and Freundlich plots for the adsorption of CR onto the three nanorod adsorbents are obtained by plotting  $C_e/q_e$  vs.  $C_e$  and  $\ln q_e$  vs.  $\ln C_e$ , respectively (given in figure 3.8). The isotherm constants and correlation coefficients were calculated and listed in table 3.2. By comparing the correlation coefficients  $r_L^2$ , it can be deduced that the experimental equilibrium adsorption data are well described by both the Langmuir and Freundlich models, but the Langmuir model is more suitable. The maximum adsorption capacity of  $103.09 \text{ mg g}^{-1}$ ,  $232.56 \text{ mg g}^{-1}$  and  $78.13 \text{ mg g}^{-1}$  was found for  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ ,  $\gamma\text{-Fe}_2\text{O}_3$ , and  $\alpha\text{-Fe}_2\text{O}_3$ , respectively. For Freundlich isotherm model, the  $n$  value between 1 and 10 indicates beneficial adsorption (Chen and Zhao, 2009).

**Table 3.2** Adsorption isotherm constants for adsorption of Congo red.

<b>Langmuir</b>	<b>Adsorbent</b>	<b><math>a_L (\text{L mg}^{-1})</math></b>	<b><math>K_L (\text{L g}^{-1})</math></b>	<b><math>q_{\max} (\text{mg g}^{-1})</math></b>	<b><math>r_L^2</math></b>	<b><math>R_L</math></b>
	$\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$	0.0022	0.224	103.09	0.996	0.82
	$\gamma\text{-Fe}_2\text{O}_3$	0.0012	0.267	232.56	0.998	0.89
	$\alpha\text{-Fe}_2\text{O}_3$	0.00064	0.048	78.13	0.995	0.999
<b>Freundlich</b>	<b>Adsorbent</b>	<b><math>K_F</math></b>	<b><math>1/n</math></b>	<b><math>r_F^2</math></b>		
	$\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$	26.5	0.3493	0.957		
	$\gamma\text{-Fe}_2\text{O}_3$	46.42	0.7434	0.993		
	$\alpha\text{-Fe}_2\text{O}_3$	8.99	0.442	0.914		

**Figure 3.8** Linearization of Langmuir plots of a)  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ , b)  $\gamma\text{-Fe}_2\text{O}_3$  and c)  $\alpha\text{-Fe}_2\text{O}_3$  and Freundlich plots of d)  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ , e)  $\gamma\text{-Fe}_2\text{O}_3$  and f)  $\alpha\text{-Fe}_2\text{O}_3$  for the adsorption of Congo red.

Comparing the  $q_{\max}$  values of the different adsorbents, it is observed that,  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanorod have higher adsorption capacity than FeC<sub>2</sub>O<sub>4</sub>.2H<sub>2</sub>O and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods.

### 3.3.7. Adsorption Kinetics

In order to investigate the adsorption processes of CR on the adsorbents, pseudo-second order kinetic model is used. The pseudo-second-order model is represented as (Rajesh et al., 2011):

$$\frac{t}{q} = \frac{1}{k_2 q_e^2} + \frac{t}{q_e} \quad (3.8)$$

And the initial adsorption rate,  $h$  (mg/g min<sup>-1</sup>), as  $t \rightarrow 0$  can be defined as:

$$h = k_2 q_e^2 \quad (3.9)$$

The initial adsorption rate ( $h$ ), the equilibrium adsorption capacity ( $q_e$ ), and the second-order constants  $k_2$  (g/mg min) can be determined experimentally from the slope and intercept of plot of  $t/q$  versus  $t$ . The best-fit values of  $h$ ,  $q_e$  and  $k_2$  along with correlation coefficients of the pseudo-second-order model for the three adsorbents are shown in table 3.3 and the pseudo-second-order plots of FeC<sub>2</sub>O<sub>4</sub>.2H<sub>2</sub>O,  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> are given in figure 3.9. The values of predicted equilibrium adsorption capacities ( $q_e$ ) showed good agreement with the experimental equilibrium uptake values. Similarly, correlation coefficients are always greater than 0.99, which also explains the good fit of the model.

**Figure 3.9** Pseudo- second-order kinetic plots of a) FeC<sub>2</sub>O<sub>4</sub>.2H<sub>2</sub>O, b)  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> and c)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>.

**Table 3.3** Second-order kinetic parameters for the removal of Congo red.

Adsorbents	$K_2$ (g mg <sup>-1</sup> min <sup>-1</sup> )	$q_e$ (mg/g)	$q_e$ (mg/g) (Experimental)	$r^2$
FeC <sub>2</sub> O <sub>4</sub> .2H <sub>2</sub> O	0.0999	39.53	39.19	1
$\gamma$ -Fe <sub>2</sub> O <sub>3</sub>	0.0933	40	39.7	1
$\alpha$ -Fe <sub>2</sub> O <sub>3</sub>	0.00891	36.23	34.23	0.9986

The maximum adsorption capacity ( $q_{\max}$ ) for the adsorption of CR on  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanorod as compared to other adsorbents is listed in table 3.4.

**Table 3.4** Comparison of Congo red adsorption capacities of various adsorbents.

Types of Adsorbent	$q_{\max}$ (mg/g)	Surface area (m <sup>2</sup> /g)	Reference
Chitosan/montmorillonite nanocomposite	54.52	22.3	(Wang and Wang, 2007)
Montmorillonite	12.70	61.4	(Wang and Wang, 2007)

$\gamma$ -Fe <sub>2</sub> O <sub>3</sub> nanoparticles	208.33	81.61	(Afkhami and Moosavi, 2010)
Chitosan Bead	162.32	-----	(Chatterjee et al., 2009)
$\gamma$ -Fe <sub>2</sub> O <sub>3</sub> nanorod	232.56	129.7	Present work
FeC <sub>2</sub> O <sub>4</sub> .2H <sub>2</sub> O nanorod	103.09	27.55	Present work
$\alpha$ -Fe <sub>2</sub> O <sub>3</sub> nanorod	78.13	22.78	Present work

Table 3.4 represents a comparison on the adsorption capacities of different adsorbents reported in literature and our prepared FeC<sub>2</sub>O<sub>4</sub>.2H<sub>2</sub>O,  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanomaterials along with their BET surface area values. It is observed that, although the commercial activated carbon possesses considerably higher surface area than the prepared  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanorod, but their maximum sorption capacities is not proportionately higher as compared to  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanorod used in this work. Again, the prepared FeC<sub>2</sub>O<sub>4</sub>.2H<sub>2</sub>O and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods possess similar surface area to other adsorbents in the table, but their maximum sorption capacities of are considerable higher than others. The above discussion indicates that the number of adsorption sites per unit surface is higher for iron oxide based materials compared to other materials studied. Hence, the prepared  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanorod can be used as an alternative efficient adsorbent than activated carbon for adsorption of Congo red from aqueous solution. This materials can also be used as efficient adsorbent for removal other organic pollutants from waste water.

### 3.4. Conclusions

In this present study, we have synthesized ferrous oxalate nanorods by a modified precipitation by using ferrous sulphate and oxalic acid as starting material and CTAB as surfactant. Then the obtained nanoparticles are calcined at higher temperature to form  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods. SEM images indicate the formation of rod shaped nanoparticles with diameter around 100-200 nm and length up to micrometres. The formation of the phase, crystallite sizes, lattice parameters, lattice strains and crystal structure are determined by XRD study. It is found that the crystallite sizes are 22.6 nm, 29.4 nm and 39.1 nm, for FeC<sub>2</sub>O<sub>4</sub>.2H<sub>2</sub>O,  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods, respectively. Then the three prepared 1-dimensional nanomaterials such as: ferrous oxalate (FeC<sub>2</sub>O<sub>4</sub>.2H<sub>2</sub>O), maghemite ( $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>) and hematite ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>) nanorods were used as adsorbent for removal of carcinogenic organic dye such as: Congo red from aqueous solution. From the adsorption study it is found that the maximum adsorption capacities of the adsorbents are 103.09 mg g<sup>-1</sup>, 232.56 mg g<sup>-1</sup> and 78.13 mg g<sup>-1</sup> for FeC<sub>2</sub>O<sub>4</sub>.2H<sub>2</sub>O,  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods respectively. This result indicates that among the three prepared 1-dimensional nanomaterials,  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanorods are the most effective adsorbent for the adsorption of Congo red from aqueous solution. This result might be due to surface charge density and high surface area to volume ratio of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanorods.

## PART B: Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> COMPOSITE NANORODS

### 3.5. Introduction

In the previous section of this chapter, adsorptive removal of Congo red dye from aqueous media has been presented using FeC<sub>2</sub>O<sub>4</sub>.2H<sub>2</sub>O,  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods. We have used the oxalate precipitation method for synthesis of the FeC<sub>2</sub>O<sub>4</sub>.2H<sub>2</sub>O,  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> rod shaped nanomaterials. In the present section, in order to improve the sorption performance of iron oxides, we have synthesized iron-tin mixed oxide (Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub>) composite nanomaterials using the same precipitation method followed by calcination as described in the previous part (part A).

One dimensional (1D) nanomaterial, including nanotubes, nanowires, nanofibers and nanorods possess superior properties like small dimension structure, high aspect ratio and unique device function compared to their bulk and microscale counterparts. Due to these properties, one dimensional (1D) nanomaterials are applied in the fields of electronics, photonics, chemical sensors, field emission devices, solar cells, lithium ion battery, hydrogen storages, adsorption, energy harvesting, nanoelectronics, optoelectronics, nanobiotechnology, nanofluidics and drug deliveries (Tekina and Saygi, 2013; Li et al., 2011; Fang et al., 2010; Dang et al., 2013). Inorganic semiconductor metal oxides (Fe<sub>2</sub>O<sub>3</sub>, ZnO, SnO<sub>2</sub>, TiO<sub>2</sub>, MnO<sub>2</sub>, CuO etc.) are the most common minerals on the Earth and their 1D nanostructure are very important for their special shapes, compositions, and chemical and physical properties associated with the 1D structural confinement (Zhai et al., 2009; Anandan et al., 2010; Zhou et al., 2010). Nowadays, researchers are much more interested in field of mixed metal oxide nanocomposite/heteronanostructures. The nanocomposites/heteronanostructures, consist of chemically distinct components, are generating novel properties arise from the strong interface interactions at the nanometer scale. The said novel properties are nonexistent in the individual component materials (Mahapatra et al., 2013; Niu et al., 2010).

Water pollution is a major global problem worldwide that leads to large alterations in the hydrological cycle and causes deaths and diseases (Xiong et al., 2013). Wastewater generated from many industries such as textile, rubber, paper, leather, plastics, cosmetic, printing, etc. contains several kinds of synthetic dyestuffs, that exhibit high color and high chemical and/or biochemical oxygen demands (COD and/or BOD) (Dawood and Sen, 2012). Decomposition of dyes gives hazardous products, that are toxic and causes severe health problem to living

beings. Thus the removal of dye effluents from aqueous media is highly essential for environmental remediation (Irama et al., 2010). There are several methods for removal of organic dyes from aqueous solution including chemical coagulation, oxidation, ion exchange, precipitation, phytoextraction, filtration, reverse osmosis, carbon adsorption, photo-degradation etc. (Setti et al., 2015). Amongst all the practiced methods, adsorption is considered to be a promising method for efficient removal of the dyes with its relative operational simplicity and high efficiency (Saikia et al., 2013). Currently, nanoparticles such as nano-carbon materials and nanosized metal oxides are mostly used for adsorption applications; because they are found to be powerful adsorbent materials due to their large specific surface area and small internal diffusion resistance (Zhang et al., 2013).

In the present investigation, we have synthesized  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> composite nanorods by a simple wet chemical method and studied the structural and magnetic properties. Then, the prepared metal oxide composite nanorods were used as adsorbents for the removal of Congo red (CR) dye molecules from aqueous solutions. The adsorption experiments such as the effects of adsorbent dose and composition, contact time, pH, and initial concentration variation were explored in batch experiments. The adsorption isotherm and kinetic studies were also carried out to elucidate the maximum adsorption capacity and nature of the adsorption. A comparative study for maximum removal capacity using different adsorbents was also reported here.

### **3.6. Materials and methods**

#### **3.6.1. Materials**

Ferrous sulphate heptahydrate (FeSO<sub>4</sub>·7H<sub>2</sub>O), oxalic acid dihydrate (H<sub>2</sub>C<sub>2</sub>O<sub>4</sub>·2H<sub>2</sub>O), cetyltrimethyl ammonium bromide (CTAB), ethanol and Congo red were procured from Merck India. Tin sulphate (SnSO<sub>4</sub>) was obtained from Sigma-Aldrich. All the chemicals were used as received without any further purification.

#### **3.6.2. Synthesis of Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> composite nanorods**

Hematite ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>) and Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> composite nanorods were synthesized by wet chemical method using FeSO<sub>4</sub>·7H<sub>2</sub>O and SnSO<sub>4</sub> as salt precursors, CTAB as structure directing agent and ethanol and double distilled water as solvent. In a typical preparation procedure, stoichiometric amount of FeSO<sub>4</sub>·7H<sub>2</sub>O and SnSO<sub>4</sub> were dissolved in distilled water with vigorous stirring to form solution-I and required amount of oxalic acid and CTAB were dissolved in ethanol with vigorous stirring to form solution-II. Then, solution-I was added to

solution-II drop wise with continuous stirring to form a yellow precipitate. The yellow precipitate changes to whitish yellow with increasing percentage of  $\text{SnSO}_4$ . After addition, the stirring was continued for another 5 hours. Then the precipitate obtained was centrifuged, washed thoroughly by ethanol and double distilled water and dried at  $80^\circ\text{C}$  for 2 hours to form ferrous oxalate-tin oxalate nanorod. The obtained composite nanorods were calcined at  $500^\circ\text{C}$  with heating rate  $10^\circ\text{C}/\text{min}$  for 2 hours to form  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  composite nanorods. In order to maintain identical processing condition for comparison of adsorption properties, we have synthesized the iron oxide using the same condition applied for the composite metal oxide synthesis. Under the adopted condition, we found  $\alpha$ -phase to be stabilizing; hence we have used  $\alpha$ -phase for comparison.

### 3.6.3. Characterization techniques

The surface morphology of the prepared nanorods was characterized by a JEOL JSM-5300 scanning electron microscope (SEM) operated at an acceleration voltage of 15 and 20.0 kV. The size of the particle and selected area electron diffraction (SAED) pattern of the  $\alpha\text{-Fe}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 6: 4) composite nanorods were observed using a high resolution transmission electron microscope (JEM-2100 HRTEM, Make-JEOL, Japan) with an acceleration voltage of 200KV. The crystalline phases were identified by means of X-ray diffraction (XRD) by a PANalytical X-ray diffractometer with  $\text{Cu K}\alpha$  radiation ( $\lambda$ )  $1.54156^\circ\text{\AA}$  at a scan rate of  $2^\circ/\text{min}$ . FTIR spectra were recorded using a Perkin-Elmer FTIR (Spectrum RX-I) spectrophotometer. Raman spectra were collected using a RAMNOR HG-2S spectrometer in a backscattering configuration, employing the 514.5 NM line of air laser as the excitation source. Specific surface area and pore size distribution (PSD) of the samples were determined from nitrogen adsorption/desorption isotherms obtained at the temperature of liquid nitrogen in an automated physisorption instrument (Autosorb-iQ, Quantachrome Instruments). Prior to the analysis, the samples were outgassed under vacuum at  $150^\circ\text{C}$  for 1.5 h. Specific surface areas were calculated according to the Brunauer-Emmett-Teller (BET) method and the pore size distributions were obtained according to the Barret-Joyner-Hallenda (BJH) method from the adsorption data. The magnetic properties of the prepared  $\alpha\text{-Fe}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe :Sn = 8:2) nanorods were obtained on a Lakeshore 7410 series vibrating sample magnetometer (VSM) at a temperature 300 K and a magnetic field of 1.5 T.

### 3.6.4. Adsorption Experiment

A stock solution of CR ( $1 \text{ g L}^{-1}$ ) was prepared in double distilled water and desired concentrations of the dye were obtained by diluting the same with double distilled water. The calibration curve of CR was prepared by measuring the absorbance of different concentrations of CR dye at  $\lambda_{\text{max}} = 498 \text{ nm}$  using UV–Vis spectrophotometer. The adsorption study was carried out by taking 50 mg each adsorbent into 20 ml of Congo red solution (100 mg/L) under stirring condition. In a batch adsorption process, adsorption experiments were conducted to observe the effects of various parameters such as: adsorbent composition, dose, time, pH, and initial concentration of Congo red. To evaluate the sorption capacity, the initial concentrations of Congo red solutions were varied in the range of 100–500 mg/L, and the dosage of adsorbents was kept 50 mg for each adsorbent into 20 ml of Congo red solution under constant stirring for 30 min. After adsorption, the solution was filtered and analyzed by UV–Visible spectrophotometer to know the absorbance. All the adsorption experiments were carried out three times in replicates and the mean data obtained were taken in results and discussion section.

## 3.7. Results and discussion

### 3.7.1. Characterization of $\text{Fe}_2\text{O}_3\text{-SnO}_2$ composite nanorods

Figure 3.10a shows the SEM image of pure  $\alpha\text{-Fe}_2\text{O}_3$ . It suggests that the obtained nanostructure exhibits rod shaped morphology with diameter around 100-200 nm and the length up to micrometers. Figures 3.10b-f represent the SEM images of  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  composites prepared by varying mole % of iron and tin salt precursors. From the images it is found that, with decreasing mole percentage of  $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$  and increasing mole percentage of  $\text{SnSO}_4$  the diameter of nanorods increases. Figure 3.10b represents the SEM image of  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 9: 1). From this image, the formation of smooth rod shaped morphology composite material is observed with a diameter slightly greater than pure  $\alpha\text{-Fe}_2\text{O}_3$ . Following the similar trend, it is found that the rod diameter gradually increases and reaches the highest value i.e. around 500-600 nm for  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 5: 5). However, it is observed that the rod shaped morphology of the composite is gradually destroyed with increasing percentage of  $\text{SnO}_2$ . The energy-dispersive spectroscopy (EDS) spectrums are shown in figure 3.10g and (h) for  $\alpha\text{-Fe}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 5: 5), respectively. Figure 3.10g spectrum demonstrates that the sample contains O, and Fe elements. Similarly from figure 3.10h, it is found that the spectrum contains O, Fe and Sn elements.

**Figure 3.10** Scanning Electron micrographs of (a)  $\alpha$ - $\text{Fe}_2\text{O}_3$ , (b)  $\text{Fe}_2\text{O}_3$ - $\text{SnO}_2$  (Fe: Sn = 9: 1), (c)  $\text{Fe}_2\text{O}_3$ - $\text{SnO}_2$  (Fe: Sn = 8: 2), (d)  $\text{Fe}_2\text{O}_3$ - $\text{SnO}_2$  (Fe: Sn = 7: 3), (e)  $\text{Fe}_2\text{O}_3$ - $\text{SnO}_2$  (Fe: Sn = 6: 4), and (f)  $\text{Fe}_2\text{O}_3$ - $\text{SnO}_2$  (Fe: Sn = 5: 5), and EDAXs of (g)  $\alpha$ - $\text{Fe}_2\text{O}_3$ , and (h)  $\text{Fe}_2\text{O}_3$ - $\text{SnO}_2$  (Fe : Sn = 5: 5).

The transmission electron micrographs of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 6: 4) materials are shown in figure 3.11. A typical TEM image of a single  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorod is given in figure 3.11a, which indicates the diameter of the rod is around 100 nm. From figure 3.11b-c, it is observed that the morphology of Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 6: 4) composite is not completely rod shaped, that means with increasing percentage of SnO<sub>2</sub> the percentage of rod shaped morphology destroyed. The result is in agreement with SEM micrographs. The crystalline structure of Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 6: 4) 1D nanorod was further analyzed by SAED pattern. The SAED pattern of the nanorod (figure 3.11d) shows bright diffraction spots, due to high crystalline nature of the sample.

**Figure 3.11** Transmission electron microscopy images of (a)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, (b and c) Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 6: 4) and (d) Electron diffraction pattern of Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 6: 4) nanorod.

Figure 3.12 shows the XRD patterns of pure  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> composite nanorods. The pure  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> shows sharp and intense diffraction peaks at  $2\theta$  values of 24.2°, 33.2°, 35.7°, 40.9°, 49.5°, 54.1°, 57.7°, 61.5°, and 64° corresponding to the presence of highly crystalline rhombohedral phase according to JCPDS file 79-0007. The Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> composites are prepared by addition of different mole % of SnSO<sub>4</sub> with FeSO<sub>4</sub>.7H<sub>2</sub>O salt precursor. It is observed that the presence of both magnetic  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> phases along with SnO<sub>2</sub> in the Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> composites, calcined at 500 °C temperature. With increasing percentages of SnSO<sub>4</sub>, the formation of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> phase is observed along with  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> phase. However, the maximum intensity peak ( $2\theta=33.2^\circ$ ) corresponds to  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> phase gradually decreases and completely disappeared after addition of 30 % SnSO<sub>4</sub>. The XRD patterns of the composite nanorods contain characteristic peaks of cubic  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> and

tetragonal  $\text{SnO}_2$  according to JCPDS No: 39-1346 and 77-0451, respectively. Generally, it is known that at calcination temperature  $500^\circ\text{C}$  the  $\gamma\text{-Fe}_2\text{O}_3$  phase is unstable: as it changes to stable  $\alpha\text{-Fe}_2\text{O}_3$  phase. But in our study, it is observed that after calcined at  $500^\circ\text{C}$  temperature, the  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  composites retain their  $\gamma\text{-Fe}_2\text{O}_3$  phase. During the transition of  $\gamma\text{-Fe}_2\text{O}_3$  to  $\alpha\text{-Fe}_2\text{O}_3$ , the thermal stability of the  $\gamma\text{-Fe}_2\text{O}_3$  phase in the pure iron oxide is different from that in the  $\gamma\text{-Fe}_2\text{O}_3\text{-SnO}_2$  composite. In pure iron oxide, the  $\gamma\text{-Fe}_2\text{O}_3 \rightarrow \alpha\text{-Fe}_2\text{O}_3$  transition occurs in the temperature higher than  $300^\circ\text{C}$  but in the prepared  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  nanocomposite system, the  $\gamma\text{-Fe}_2\text{O}_3$  stabilized after heating at  $500^\circ\text{C}$  for 2 hours. The existence of the  $\gamma\text{-Fe}_2\text{O}_3$  crystal phase in the presence of  $\text{SnO}_2$  at higher temperature can be caused by diffusion hindrances to the motion of atoms during structure transformation and an increased concentration of cationic vacancies, which stabilize the spinel structure of  $\gamma\text{-Fe}_2\text{O}_3$ . Maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ) is a metastable form, and the presence of  $\text{SnO}_2$  in the nanocomposite electively stabilizes this form since the activation energy is substantially increased (Lal et al., 2003; Ivanovskaya et al., 2008).

**Figure 3.12** X-ray diffraction patterns of (a) pure  $\alpha\text{-Fe}_2\text{O}_3$ , (b)  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 9: 1), (c)  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 8: 2), (d)  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 7: 3), (e)  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 6: 4), and (f)  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 5: 5).

Figure 3.13 shows the FTIR spectra of calcined  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorod and Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> composite nanorods. In figure 3.13a pattern, the peak at 644 cm<sup>-1</sup> is due to longitudinal absorption (Au) and peaks at 572 and 490 cm<sup>-1</sup> are due to transverse absorption (Eu) of Fe-O vibrational mode of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> (Ramesh et al., 2010). Figures 3.13b-f show the FTIR spectra of Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> composite nanorods. The above mentioned peaks of pure  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> are not observed in the FTIR spectra of Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> composite. In composite nanorods, the peak at 632 cm<sup>-1</sup> is due to Fe-O, which is the characteristic peak of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> (maghemite). Again, peaks at 470 and 558 cm<sup>-1</sup> are due to O-Sn-O and Sn-O stretching vibration of SnO<sub>2</sub>, respectively (Zhang et al., 2011). Furthermore, the presence of a small peak in every pattern is observed in between 3000 to 4000 cm<sup>-1</sup>. It is due to O-H mode; which indicates the presence of water of crystallization in the materials.

**Figure 3.13** Fourier transform infrared spectra of (a)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, (b) Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 9: 1), (c) Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 8: 2), (d) Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 7: 3), (e) Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 6: 4), and (f) Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 5: 5) nanorods.

Raman Spectra of the calcined  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorod and Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> composite nanorods are shown in figure 3.14. The spectrum of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> (figure 3.14a) contains peaks at 216, 276, 388, 502 and 587 cm<sup>-1</sup>. The peaks at 216 and 502 cm<sup>-1</sup> are assigned to A<sub>1g</sub> modes and the remaining three peaks at 276, 388 and 587 cm<sup>-1</sup> are assigned to E<sub>g</sub> modes of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>. In

figures 3.14b-f, the presence of peaks around at 344, 515 and 720  $\text{cm}^{-1}$  are due to  $T_{2g}$ ,  $E_g$  and  $A_{1g}$  modes of  $\gamma\text{-Fe}_2\text{O}_3$ , respectively (Jubb and Allen, 2010; Tamm et al., 2012). Moreover, with increasing percentage of  $\text{SnO}_2$  in the composite nanostructures the formation of  $\gamma\text{-Fe}_2\text{O}_3$  are observed and the peak intensity of  $\alpha\text{-Fe}_2\text{O}_3$  is gradually decreased and completely disappeared after 30 % addition of  $\text{SnSO}_4$ ; this may be due to  $\text{SnO}_2$ , which acts as a gamma stabilizer. Again, the composites contain peaks at around 479 and 635  $\text{cm}^{-1}$ . The peak at 479  $\text{cm}^{-1}$  can be assigned to  $E_g$  mode of  $\text{SnO}_2$ , which is related to the vibration of oxygen in the oxygen planes and peak at 635  $\text{cm}^{-1}$  can be assigned to  $A_{1g}$  vibrational mode of  $\text{SnO}_2$  (Shi et al., 2010).

**Figure 3.14** Room temperature Raman spectra of (a)  $\alpha\text{-Fe}_2\text{O}_3$ , (b)  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 9: 1), (c)  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 8: 2), (d)  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 7: 3), (e)  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 6: 4), and (f)  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 5: 5).

The Brunauer–Emmett–Teller (BET) surface areas were obtained from nitrogen adsorption and desorption isotherms. The nitrogen adsorption and desorption isotherms are shown in figure 3.15. The BET surface area of pure  $\alpha\text{-Fe}_2\text{O}_3$  nanorod was found to be very low i.e. 22.785  $\text{m}^2/\text{g}$ . But in case of composites the surface area increases. The surface area values are 70.676, 101.13, 66.866, 59.797, and 46.027  $\text{m}^2/\text{g}$ , for  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 9: 1),  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 8: 2),  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 7: 3),  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 6: 4) and  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 5: 5), respectively. This indicates with increasing percentages of  $\text{SnO}_2$  in the composites the surface area increases up to 20 % of  $\text{SnO}_2$  addition and then gradually decreases. The enhanced surface area of the composite than that of pure  $\alpha\text{-Fe}_2\text{O}_3$  may be due to the presence of  $\gamma\text{-Fe}_2\text{O}_3$  phase in the composite.

**Figure 3.15** N<sub>2</sub> adsorption-desorption isotherm of (a)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, (b) Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 9: 1), (c) Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 8: 2), (d) Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 7: 3), (e) Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 6: 4), and (f) Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 5: 5).

We have investigated the evolution of magnetic hysteresis loop of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorod and Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 8: 2) composite nanorod through VSM at room temperature (shown in figure 3.16). The unsaturated magnetic hysteresis loop is observed for  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorod at an applied field of 1.5 T, which indicates a weak ferromagnetic behavior (Yogi and Varshney, 2013). This is due to the incompleteness of magnetic domain orientation, which may require

sufficient high magnetic field for saturation. Whereas for Fe<sub>2</sub>O<sub>3</sub>–SnO<sub>2</sub> (Fe: Sn = 8: 2) composite nanorod, a perfect saturated hysteresis loop obtained (with saturation magnetization  $M_s = 25.23$  emu/g) at the same magnetic field. The presence of SnO<sub>2</sub> nano domains may promote the complete orientation of magnetic of magnetic domain of stable  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> in the latter case. The interesting result in the composite is of nearly zero remnant magnetization at zero fields. But the saturation magnetization is sufficiently high, which suggests the transition of weak ferromagnetic behavior of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> to the superparamagnetic behavior of Fe<sub>2</sub>O<sub>3</sub>–SnO<sub>2</sub> (Fe: Sn = 8: 2) composite nanorod (Wu et al., 2009; Dai et al., 2012).

**Figure 3.16** Magnetization curves of (a)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and (b) Fe<sub>2</sub>O<sub>3</sub>–SnO<sub>2</sub> (Fe: Sn = 8: 2) composite nanorod before and after magnetic separation by an external magnetic field at 300 K temperature.

### 3.7.2. Adsorption studies for Congo red dye removal

The prepared Fe<sub>2</sub>O<sub>3</sub>–SnO<sub>2</sub> mixed oxide composite nanorods have been used as adsorbents for **removal** of Congo red dye from aqueous system. Batch adsorption experiments were carried out by varying adsorbent dose, pH, contact time, initial concentration using 20 ml of Congo red dye (100 mg/L) solution in a 50 ml cleaned and capped glass bottle.

After adsorption, the amount of adsorbed  $q_e$  is calculated by equation (Klett et al., 2014):

$$q_e = \frac{c_0 - c_e}{w} V \quad (3.10)$$

where  $q_e$  is the amount of adsorption at equilibrium in mg g<sup>-1</sup>,  $C_0$  &  $C_e$  are the initial and equilibrium concentration of the dye in mg L<sup>-1</sup>,  $V$  is the volume of the dye solution taken in litre and  $w$  is the weight of the nanorod (adsorbent) in grams.

### 3.7.2.1. Effect of adsorbent dose and composition

Adsorbent dosage is one of the most important parameters that have been considered to determine the optimum condition for the performance of adsorption. As insufficient dosage or overdosing would result in poorer performance in adsorption. Therefore, it is significant to determine the optimum dosage in order to minimize the cost and sludge formation and also to obtain the optimum condition for performance. Similarly, by varying different adsorbent compositions, the best adsorbent can be determined. The effect of adsorbent doses and composition of adsorbent on the removal of CR using  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> composite nanorods was studied at pH=7.6 (pH at normal condition) for 20 ml of 100 mg/L CR solution and 30 min contact time. The result obtained is represented in figure 3.17. From figure 3.17a it is observed that, the percentage removal of CR dye increases with increasing percentage of SnO<sub>2</sub> from 0 to 20 % in the Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> composites. It is due to the existence of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> instead of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> in the presence of SnO<sub>2</sub>. The enhanced performance could be mainly attributed to the large surface area of the nanoparticles, as well as the electrostatic attraction between the  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> surfaces and CR. On further increase in amount of SnO<sub>2</sub> (Fe: Sn=8: 2 to Fe: Sn= 5: 5), it is found that the percentage of removal of CR decreases. This may be due to decrease in amount of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> in the composite from Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 8: 2) to Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 5: 5). So, Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 8: 2) is regarded as the best adsorbent for removal of CR among the series of composite nanorods prepared and hence it has been selected as the adsorbent for further study. It is also observed there is a continuous increase in percentage of removal of CR with increase in adsorbent dose up to 0.05 g of Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 8: 2). This may be due to an increase in number of active sites of the adsorbent material with increasing amount of the adsorbent. A further increase in the amount of the adsorbent does not bring any considerable change in the adsorption i.e. approximately straight line or adsorption saturation was observed thus 0.05 g was chosen as the optimum amount for all studies of the adsorption.

### 3.7.2.2. Effect of contact time

The time of contact of adsorbate and adsorbent plays a significant role for the removal of pollutant species from aqueous solution during batch experimental studies. It is helpful in understanding the amount of dye adsorbed at various time intervals by a fixed amount of the adsorbent. In this section 0.05 g of Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 8: 2) adsorbent was used in 20 ml 100 mg/L of CR solution maintaining pH=7.6 (normal pH), with varying time from 0 min to 60 min. From figure 3.17b, it is found that there is a consistent increase in percentage of

removal up to 30 min and the adsorption equilibrium is attained after 30 min of contact time. At the initial stage of adsorption, CR removal can be rapid due to surface adsorption (external surface adsorption) upto 30 min. In the later stage, rate of adsorption is slower because sorption occurred via transportation of surface-adsorbed dye to the internal adsorption sites of the adsorbent (internal surface adsorption) (Hou et al., 2012). As a result the rate of adsorption decreased and a saturation stage was attained due to the accumulation of the adsorption sites by the dye ions. It is found that, 99.9 % percentage of CR is removed within 30 min of contact time. So, agitation time of 30 min was selected for further studies.

**Figure 3.17** Effect of (a) amount of adsorbents and compositions of composite, (b) time for  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 8: 2), (c) pH for  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 8: 2), and (d) concentration for  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 8: 2), on removal of Congo red (CR) dye.

#### Adsorption Kinetics

In order to investigate the adsorption processes of CR on the adsorbents, the applicability of the pseudo-first-order and pseudo-second-order model was tested and the best fit model was selected according to the linear regression correlation coefficient,  $R^2$  value. The pseudo-second-order model is represented as (Bayazit et al., 2010):

$$\frac{t}{q} = \frac{1}{k_2 q_e^2} + \frac{t}{q_e} \quad (3.11)$$

And the initial adsorption rate,  $h$  ( $\text{mg/g min}^{-1}$ ), as  $t \rightarrow 0$  can be defined as:

$$h = k_2 q_e^2 \quad (3.12)$$

The initial adsorption rate ( $h$ ), the equilibrium adsorption capacity ( $q_e$ ), and the second-order constants  $k_2$  ( $\text{g/mg min}$ ) can be determined experimentally from the slope and intercept of plot of  $t/q$  versus  $t$ . The values of  $R^2$ ,  $q_e$  and  $k_2$  of the pseudo-second-order model for the adsorbent are 1, 40  $\text{mg/g}$  and  $0.89 \text{ g mg}^{-1} \text{ min}^{-1}$  respectively and the pseudo-second-order plot is given in figure 3.18. The calculated value of  $q_e$  is in good agreement with the experimental values (i.e. 39.96  $\text{mg/g}$ ). Similarly, correlation coefficients are always greater than 0.99, which also explains the good fit of the model.

**Figure 3.18** Pseudo-second-order kinetic plots for adsorption of Congo red dye by  $\text{Fe}_2\text{O}_3$ – $\text{SnO}_2$  (Fe: Sn = 8: 2) composite nanorod.

#### 3.7.2.3. Effect of pH on adsorption

Original pH of Congo red solution (100  $\text{mg/L}$ ) is about 7.6. It was seen that the dye solution changes its color from red to dark blue when pH was adjusted in highly acidic range and becomes dark blue in highly basic range i.e., pH 9 and above. Therefore, the removal of CR from aqueous solution by  $\text{Fe}_2\text{O}_3$ – $\text{SnO}_2$  (Fe: Sn = 8: 2) nanocomposite adsorbent was studied by varying the pH of the solution over the range of 3-8. The pH of the solution was adjusted by using 0.01  $\text{mol/L}$  HCl or NaOH solutions. The results obtained are shown in the figure 3.17c. For 100  $\text{mg/L}$  dye concentration, it is observed that the percentage of removal increases from pH 3 to pH 5 and then the percentage of removal remain almost the same up to pH 8. These results can be explained as follows. In acidic pH range (i.e. pH 3-5), both the

adsorbent surface and dye molecules are protonated and electrostatic attraction does not exist. Hence, the percentage of adsorption is comparatively less at lower pH values. As the pH of the system increases, the number of positively charged sites decreases and the surface of the adsorbent gets hydroxylated. Congo red dye molecules contain amine group ( $-\text{NH}_2$ ) groups. So that the adsorption may occur due to strong hydrogen bonds ( $\text{O}\cdots\text{H}-\text{N}$  and  $\text{O}-\text{H}\cdots\text{N}$ ) between  $-\text{NH}_2$  functional groups of adsorbate and surface hydroxyl ( $-\text{OH}$ ) groups on the nanoadsorbent surface (Wu et al., 2013).

According to Wei et al., Congo red is adsorbed onto the surface of metal oxides by coordination effect between the metal ions (i.e.  $\text{Fe}^{3+}$  and  $\text{Sn}^{4+}$ ) and amine ( $-\text{NH}_2$ ) groups of the Congo Red molecules (Wei et al., 2013).

Hence, the mechanism of adsorption of Congo red on the surface of the composite nanoadsorbent mainly attributed to two reasons: a) hydrogen bonds between surface hydroxyl ( $-\text{OH}$ ) groups of adsorbent and amine ( $-\text{NH}_2$ ) groups of Congo red, and b) the surface coordination effects between metal ions of adsorbent and amine groups of Congo red dye molecules.

#### *3.7.2.4. Effect of initial dye concentration on adsorption*

In this section, 0.05 g of  $\text{Fe}_2\text{O}_3\text{--SnO}_2$  (Fe: Sn = 8: 2) nanocomposite was used in each 20 ml of CR solution with concentration ranging from 100 mg/L to 500 mg/L and the agitation time was kept 30 min. The percentage removal of Congo red with change in concentration of the solution is shown in figure 3.17d. It is found that with the increase in initial dye concentration, the percentage removal decreases while the equilibrium adsorption capacity of the adsorbent increases. This is probably due to a high driving force for mass transfer in high dye concentration.

#### *Adsorption Isotherm*

To describe the adsorption behavior of Congo red by  $\text{Fe}_2\text{O}_3\text{--SnO}_2$  (Fe: Sn = 8: 2) nanocomposite adsorbent, we have studied adsorption isotherms. The most common models such as Freundlich and Langmuir equations are used for investigation of this study.

#### *Langmuir isotherm*

The Langmuir isotherm model assumes monolayer coverage of adsorbate on a homogeneous adsorbent surface. This model does not consider surface heterogeneity of the sorbent. It assumes adsorption will take place only at specific sites on the adsorbent (Bayazit, 2014).

The linear form of the Langmuir isotherm is:

$$\frac{C_e}{q_e} = \frac{1}{K_L q_{\max}} + C_e/q_{\max} \quad (3.13)$$

where  $K_L$  is the Langmuir constant related to the energy of adsorption,  $q_{\max}$  is the maximum adsorption capacity corresponding to complete monolayer coverage ( $\text{mg g}^{-1}$ ), which depends upon the number of adsorption sites. The values of  $q_{\max}$  and  $K_L$  are calculated from the slopes and intercepts of the straight lines of plot of  $C_e/q_e$  versus  $C_e$  (figure 3.19a).

#### Freundlich isotherm

The Freundlich isotherm model describes the surface heterogeneity of the sorbent and considers multilayer adsorption with a heterogeneous energetic distribution of active sites, accompanied by interactions between adsorbed molecules (Yu et al., 2013).

The linear form of the Freundlich isotherm is:

$$\ln q_e = \ln K_F + 1/n \ln C_e \quad (3.14)$$

where  $C_e$  is the equilibrium concentration ( $\text{mg L}^{-1}$ ),  $q_e$  is the amount adsorbed at equilibrium ( $\text{mg g}^{-1}$ ) and  $K_F$  and  $n$  are Freundlich constants, related to the extent of the adsorption and the degree of nonlinearity between solution concentration and adsorption, respectively.  $K_F$  and  $(1/n)$  can be determined from the linear plot of  $\ln q_e$  versus  $\ln C_e$  (figure 3.19b).

The values of  $q_{\max}$ ,  $K_L$ ,  $K_F$ ,  $1/n$  and the correlation coefficients for Langmuir ( $r_L^2$ ) and for Freundlich ( $r_F^2$ ) are given in table 3.5. It can be seen that the Langmuir model yields a much better fit than the Freundlich model. According to Langmuir model the maximum adsorption capacity ( $q_{\max}$ ) maximum adsorption capacity is found to be 181.82  $\text{mg/g}$ .

**Figure 3.19** Linearization of a) Langmuir plots and b) Freundlich plots for the adsorption of Congo red dye by Fe<sub>2</sub>O<sub>3</sub>-SnO<sub>2</sub> (Fe: Sn = 8: 2) composite nanorod.

Fe <sub>2</sub> O <sub>3</sub> –SnO <sub>2</sub> (Fe: Sn = 8: 2) composite nanorod	182	Present Work

The maximum adsorption capacity (q<sub>max</sub>) for the adsorption of CR on Fe<sub>2</sub>O<sub>3</sub>–SnO<sub>2</sub> (Fe: Sn = 8: 2) composite nanorod compared to other adsorbents is listed in table 3.6. It is observed that the prepared Fe<sub>2</sub>O<sub>3</sub>–SnO<sub>2</sub> (Fe: Sn = 8: 2) composite nanorod is an efficient adsorbent for adsorption of Congo red from aqueous solution.

#### 3.7.2.5. Desorption and reusability study

Desorption of dyes from adsorbent and re-generation of the adsorbent is an important issue in view of re-usability of the adsorbent. With rising prices of raw materials and wastewater treatment processes, the attractiveness of product recovery processes has increased significantly. The main objective of the regeneration process is to restore the adsorption capacity of exhausted adsorbent and to recover valuable components present in the adsorbed phase. Desorption study was performed by mixing 0.05 g CR loaded Fe<sub>2</sub>O<sub>3</sub>–SnO<sub>2</sub> (Fe: Sn = 8: 2) nanocomposite with 20 ml of 0.01 mol L<sup>-1</sup> NaOH solution and desorption was carried out for 2 hours. Then the concentration of eluted CR was measured to calculate the amount of CR desorbed. For regeneration studies, successive adsorption–desorption processes were

carried out for four consecutive cycles which is shown in figure 3.20. The figure shows that about 99 and 91 % CR effectively removed on the first cycle and the second cycle, respectively. After that, the removal capacity of the adsorbent decreases as the number of cycles increases. Although there is a gradual decrease in removal capacity with increasing cycle numbers, it is observed the dye adsorption capacity still remained more than 80 % at the end of the fourth cycle.

**Figure 3.20** Reusability of  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 8: 2) nanocomposite adsorbent for adsorption/desorption of Congo red during four cycles.

The FTIR spectra and FE-SEM of  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 8: 2) nanocomposite after different adsorption cycles were carried out and shown in figure 3.21 and figure 3.22 respectively. From the figure 3.21 it is observed that along with the peaks of composite (previously discussed), some additional peaks are present. Peaks at  $3429\text{ cm}^{-1}$  and  $1612\text{ cm}^{-1}$  can be attributed to the N-H & C=C stretching vibration of the functional groups present in CR dye. New peaks around  $1370$  and  $1180\text{ cm}^{-1}$  are due to the framework vibration of benzene rings of CR dye. Another peak is observed at  $1038\text{ cm}^{-1}$ , which is due to the S=O stretching vibration of CR dye.

Figure 3.22 shows the FE-SEM images of CR adsorbed  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 8: 2) nanocomposite after different adsorption cycles. From the figure it is observed that, the rod shaped morphology of the composite nanorod retained up to three consecutive cycles. Thus, the  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 8: 2) nanocomposite can be effectively reused for CR adsorption from waste water. It is also observed from the SEM images that agglomeration of rod shaped composite nanomaterials takesplace with successive adsorption cycles. Due to the aggregated

form, the surface exposure of nanorods towards dye molecules decreases and this is the primary cause of decrease in sorption capacity.

**Figure 3.21** FTIR spectra of CR adsorbed  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe : Sn = 8 : 2) after (a) 1<sup>st</sup>, (b) 2<sup>nd</sup>, (c) 3<sup>rd</sup> and (d) 4<sup>th</sup> adsorption cycle.

**Figure 3.22** FESEM images of CR adsorbed  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 8: 2) after (a) 1<sup>st</sup>, (b) 2<sup>nd</sup>, (c) 3<sup>rd</sup> and (d) 4<sup>th</sup> adsorption cycle.

### 3.8. Conclusions

We have synthesized  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  composite nanorods by a wet chemical route using CTAB as structure directing agent. SEM and TEM results represent the formation of uniform nanorods with typical diameter 100-200 nm. It was also observed that, the shape and uniformity of the composite nanorods changes with increasing percentage of  $\text{SnO}_2$ . The XRD studies confirmed the formation of  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  mixed oxide nanocomposites. However, upon addition of  $\text{Sn}^{+4}$  ions to  $\text{Fe}_2\text{O}_3$  matrix the formation of  $\gamma\text{-Fe}_2\text{O}_3$  phase was observed at 500 °C calcination temperature. With an increase in concentration of  $\text{Sn}^{+4}$ , the peaks corresponds to  $\gamma\text{-Fe}_2\text{O}_3$  phase became prominent and peak intensity of  $\alpha\text{-Fe}_2\text{O}_3$  gradually reduced. This observation indicates that metastable  $\gamma\text{-Fe}_2\text{O}_3$  phase was selectively stabilized in case of composite oxides. The formation of mixed oxide composite was further confirmed by Raman studies. The obtained  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  composite nanorods were used as adsorbent for removal of Congo red dye from aqueous solution. All the composites show better adsorption than that the  $\alpha\text{-Fe}_2\text{O}_3$  nanorod and  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 8: 2) composite nanorod was found to be most promising adsorbent among the series for decontamination of CR dye within a short contact time of 30 min.

## CHAPTER-4

### IRON OXIDE IMPREGNATED MESOPOROUS MCM-41: SYNTHESIS, CHARACTERIZATION AND ADSORPTION STUDIES

#### 4.1. Introduction

Mesoporous materials such as MCM-41, MCM-48, and SBAs have been the subject of intensive research in the field of adsorption and heterogeneous catalysis because of their high surface area, high pore volume, favorable and controllable pore uniformity, high hydrophobicity and relatively high thermal stability (Huang et al., 2013; Pouretedal and Ahmad, 2012; Jyothi et al., 2012). MCM-41 (Mobil composite material number 41, first discovered in 1992) consists of hexagonal array of uniformly sized one-dimensional pore geometry with a pore diameter of 2 to 10 nm (Ng et al., 2013). Hence, ordered mesoporous MCM-41 has been used for adsorption of various contaminants from water because of its excellent removal capacity. The modification of MCM-41 for the adsorption is very helpful in the improvement of the adsorption capacity and selectivity because of specific interactions between adsorbents and adsorbates (Santos et al., 2013). Specially, incorporation of heteroatoms such as Fe, Al, Cr and so on into the primarily inert frameworks make the structure more potential for the application in the field of catalysis and adsorption (Li et al., 2013; Parida and Dash, 2010). Due to the occurrence of high surface area of about 1000 m<sup>2</sup>/g, porosity and amorphous structure, there is a possibility of incorporation of transition metal ion inside the mesoporous framework by substitution of Si atoms in regular tetrahedral positions (Rath and Parida, 2011; Elias et al., 2011; Rana and Viswanathan, 1998).

Among the heteroatoms, iron atom incorporated into the silica framework generates the strong acid sites. As a result of which Fe-containing mesoporous silicates have shown better performance towards catalytic activity and adsorption. Very recently, several attempts have been made for extensive study of iron-containing mesoporous materials MCM-41(Fe<sup>3+</sup>) due to its considerable interest for various applications, especially for catalytic and adsorption properties (Li et al., 2012). Lan et al. (2013) have used iron-loaded MCM-41 (Fe/MCM-41), which was synthesized by a hydrothermal method, as an effective catalyst for the ozonation of p-chlorobenzoic acid. Wang et al. (2002) have reported the epoxidation of styrene with hydrogen peroxide by hydrothermally prepared Fe–MCM-41 catalyst. Bengoa and co-workers (2010) have synthesized silylated Fe/MCM-41 for catalyst in Fischer–Tropsch

reaction. Chen et al. (2011) have used magnetic nanosorbent  $\text{Fe}^{3+}$ -magMCM-41 for removal of chromium (VI) oxyanions from distilled, tap, mountain stream and river waters. Wantala et al. (2010) have synthesized Fe-MCM-41 by hydrothermal method for the removal of arsenate from aqueous solution. Similarly, other research groups have used Fe-MCM-41 as catalyst for the oxidative desulfurization dibenzothiophene (Li et al., 2012), synthesis of multi-wall carbon nanotubes by the pyrolysis of ethanol (Zhao et al., 2010), synthesis of diphenylmethane (Preethia et al., 2011), acetylation of 1, 2-dimethoxybenzene (Bachari et al., 2012), phenol hydroxylation (Choi et al., 2006), wet oxidation of phenol (Khieu et al., 2009), and phenol hydroxylation and for Friedel–Crafts alkylation (Jiang et al., 2012). Generally, MCM-41 and Fe-MCM-41 were prepared by hydrothermal method. However, a wet chemical method is the easiest method to prepare MCM-41 and metal doped MCM-41 with high yield and purity. In the previous chapter, we have synthesized iron oxide nanorods and iron oxide-tin oxide composite nanorods by a chemical precipitation method. The prepared nanomaterials were found to be efficient adsorbents for removal of an anionic dye (Congo red) from aqueous media. This chapter describes the synthesis of iron oxide impregnated mesoporous MCM-41, which can afford enough surface area along with nanosized iron oxide particles dispersed inside the porous matrix for further enhancement of sorption activities. Generally, the surface of MCM-41 is negatively charged in aqueous medium because its surface acquires a negatively charged SiO<sup>-</sup>-state when in contact with water by the dissociation of silanol groups, and hence it can be used as an adsorbent to remove cationic dye from wastewater (Zhang et al., 2014; Jambhrunkar et al., 2014). Therefore, we have used a cationic dye (Methylene blue) for adsorption purpose in this work.

In the present work, we have prepared MCM-41 and Fe-MCM-41 (iron oxide dispersed MCM-41) using a wet chemical technique. Then, the prepared materials were employed for adsorptive removal of methylene blue (MB) dye from aqueous media and a comparative study was carried out by evaluating equilibrium isotherms and kinetic data for selection of the more effective adsorbent among them.

## **4.2. Materials and Methods**

### **4.2.1. Chemicals Used**

Tetraethyl orthosilicate (TEOS), Cetyltrimethylammonium bromide (CTAB), Ammonium hydroxide ( $\text{NH}_4\text{OH}$ ), and ferrous sulphate ( $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ ) from Merck India pvt. Ltd. and

Ethanol from Merck Germany pvt. Ltd. All the reagents used in the synthesis and catalytic study were of analytical grade and used as received without further purification.

#### 4.2.2. Synthesis of MCM-41

2.4 g of CTAB was dissolved in 120 mL double distilled water. Then 8 mL of  $\text{NH}_4\text{OH}$  and 10 mL of TEOS was added slowly with continuous stirring and then the stirring was continued for 12 h. Then the solid product was filtered, washed repeatedly with water and ethanol, and calcined at 823 K for 5 h.

#### 4.2.3. Synthesis of Iron oxide dispersed MCM-41 (Fe-MCM-41)

0.05 g of  $\text{FeSO}_4 \cdot \text{H}_2\text{O}$  was dissolved in 10 mL of double distilled water and 0.5 g of MCM-41 was taken in 10 mL of ethanol. The two solutions of  $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$  and MCM-41 was mixed and stirred for 3 h to form  $\text{Fe}^{2+}$  dispersed MCM-41. Then the obtained  $\text{Fe}^{2+}$  dispersed MCM-41 was filtered, washed with ethanol, dried at room temperature and calcined at 823K for 4 h to form Iron oxide dispersed MCM-41. A schematic illustration of the preparation process of MCM-41 and Fe-MCM-41 is shown in figure 4.1.

**Figure 4.1** Schematic illustration of the preparation process of MCM-41 and Fe-MCM-41.

#### 4.2.4. Characterization techniques

Small and wide X-ray diffraction (XRD) measurements of the mesoporous materials were carried out using  $\text{Cu K}\alpha$  radiation on a Rigaku Ultima-IV X-ray diffractometer. X-ray

photoelectron spectroscopy (XPS) was determined using a VG Scientific ESCA LAB Mk-II spectrometer with Al K $\alpha$  radiation (1486.6 eV) at a takeoff angle at 45°. The surface morphology of the prepared materials was characterized by a Nova Nano SEM 450 field emission scanning electron microscopy (FE-SEM) operated at an acceleration voltage of 15 and 20.0 kV. FTIR spectra were recorded using Perkin-Elmer FTIR (Spectrum RX-I) spectrophotometer. Specific surface area and pore size distribution (PSD) of the samples were determined from nitrogen adsorption/desorption isotherms obtained at the temperature of liquid nitrogen in an automated physisorption instrument (Autosorb-iQ, Quantachrome Instruments). Prior to the analysis, the samples were outgassed under vacuum at 150 °C for 1.5 h. Specific surface areas were calculated according to the Brunauer-Emmett-Teller (BET) method, and the pore size distributions were obtained according to the Barret-Joyner-Hallenda (BJH) method from the adsorption data.

#### 4.2.5. Adsorption experiment

For the removal of MB dye from water, the adsorption experiments were carried out using the prepared MCM-41 and Fe-MCM-41 adsorbents at room temperature. A stock solution of MB (1 g L<sup>-1</sup>) was prepared and desired concentrations (ranging from 50 to 500 mg L<sup>-1</sup>) of the dye were obtained by diluting the same with double distilled water. The calibration curve of MB was prepared by measuring the absorbance of different concentrations of the samples at  $\lambda_{\text{max}} = 664 \text{ nm}$  using UV-vis spectrophotometer. The amount of adsorption  $q_e$  is calculated by equation (Durán-Jiménez et al., 2014):

$$q_e = \frac{C_0 - C_e}{w} V \quad (4.1)$$

where  $q_e$  is the amount of adsorption at equilibrium in mg g<sup>-1</sup>,  $C_0$  &  $C_e$  are the initial and equilibrium concentration of the dye in mg L<sup>-1</sup>,  $V$  is the volume of the dye solution taken in litre and  $w$  is the weight of the nanorod (adsorbent) in gram. All the adsorption experiments were carried out three times in replicates and the mean data obtained were taken in results and discussion section.

### 4.3. Results and Discussion

#### 4.3.1. Characterization of MCM-41 and Fe-MCM-41 nanomaterials

Figure 4.2 shows the SAXS patterns of MCM-41 and Fe-MCM-41 nanomaterials. The patterns consist of one pronounced peak each at  $2\theta$  value 2.68° and 2.42° for MCM-41 and Fe-MCM-41, respectively and these peaks are indexed to (100) reflection plane. Again, two low incensed peaks each at  $2\theta = 4.29^\circ$  and  $4.7^\circ$  due to the reflection from (110) and (200)

planes, respectively for MCM-41 and at  $2\theta = 4.23^\circ$  and  $4.65^\circ$  due to the reflection from (110) and (200) planes, respectively for Fe-MCM-41 were observed. This indicates the formation of a well-ordered mesoporous material and these peaks are generally indexed according to the hexagonal regularity of MCM-41 (Jiang et al., 2012). These results are in good agreement with previous observations reported by Li et al. (2012) and Lan et al. (2013). However it is observed that, with the incorporation of iron atoms into the framework of MCM-41, the intensity of the peaks of Fe-MCM-41 sample decreased with a peak broadening of characteristics peak (100) (Yu et al., 2014). It indicates the possibility of formation of iron oxide cluster inside the channel as a result of calcinations at high temperature.

**Figure 4.2** SAXS patterns of MCM-41 and Fe-MCM-41.

Wide angle XRD patterns for the calcined MCM-41 and Fe-MCM-41 are shown in figure 4.3. No characteristic peaks of iron oxide and other Fe species were observed for Fe-MCM-41, which suggested that iron oxide species might be present as finely dispersed nano dimensional particles (at least in one dimension) below the detection limits of x-ray and/or as amorphous particles in the framework of MCM-41.

**Figure 4.3** Wide angle XRD patterns of MCM-41 and Fe-MCM-41.

In order to understand the nature of the interaction between Fe ions and MCM-41 mesoporous materials, the Fe-MCM-41 sample was characterized by the XPS technique, and the results are shown in Figure 4.4. A very complex line-shape Fe 2p spectrum (figure 4.4a) is observed due to satellite structure and multiplet effects. The Fe 2p spectrum can be fitted with ten synthetic peaks. The peaks correspond to 707.5, 710.3 and 712.8 eV are associate with  $\text{Fe}^0$ ,  $\text{Fe}^{2+} 2p_{3/2}$  and  $\text{Fe}^{3+} 2p_{3/2}$  spin states, respectively. Again, presence of peaks at 723.85 and 726.28 eV is due to  $\text{Fe}^{2+} 2p_{1/2}$  and  $\text{Fe}^{3+} 2p_{1/2}$  spin states, respectively. From the result it is observed that the iron oxide nanoparticles are a mixture of FeO and  $\text{Fe}_2\text{O}_3$ . Other smaller peaks are due to satellite peaks of both  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  ions. The BE values of Fe peaks are shown in table 4.1. A shifting of BE values around 0.5-1 eV is observed compared with literature (Davoisne et al., 2008; Carrillo et al., 2013); due to the presence of small amounts iron ions inside the MCM-41 frame work, where they have the possibility to form Fe-O-Si bonds. The Si 2p spectrum of the Fe-MCM-41 is shown in figure 4.4b. This spectrum with BE=107.6 eV, is the characteristic spectrum for the silicates. From figure 4.4c, it is observed that the spectrum can be fitted with two peaks. The peak at 285.7 is due to C 1s spin state and peak at 288.7 due to a very low concentration of carbon. The value of BE indicates that the origin of this carbon is the environmental contamination of the sample surface (Stefanis et al., 2007). The spectrum of O 1s (figure 4.4d) is composed of a single peak at 536.8 eV.

**Figure 4.4** X-ray photoelectron spectra of (a) Fe 2p, (b) Si 2p, (c) C 1s, and (d) O 1s of Fe-MCM-41.

**Table 4.1** Binding energies of the peaks determined for Fe spectrum of Fe-MCM-41.

$\text{Fe}^0$	$\text{Fe}^{2+}$ $2p_{3/2}$	$\text{Fe}^{3+}$ $2p_{3/2}$	$\text{Fe}^{2+2}$ $p_{1/2}$	$\text{Fe}^{3+}$ $2p_{1/2}$	$\text{Fe}^{2+}$ sat. $2p_{3/2}$	$\text{Fe}^{3+}$ sat. $2p_{3/2}$	$\text{Fe}^{2+}$ sat. $2p_{1/2}$	$\text{Fe}^{3+}$ sat. $2p_{1/2}$
707.5	710.3	712.8	723.8	726.3	715.1 & 718.1	721.2	729.8	732.3

**Figure 4.5** Low and high magnification FESEM images of (a, a') MCM-41 and (b, b') Fe-MCM-41.

The microstructure and morphology of the prepared mesoporous MCM-41 and Fe-MCM-41 nanomaterials were characterized by FESEM and HRTEM and are given in figure 4.5 and figure 4.6, respectively. Spherical particles having diameter in the range of 200-400 nm and mesoporous structure are observed in the low and high magnification FESEM images of MCM-41 (figure 4.5a, a'). In case of Fe-MCM-41, when iron atom is incorporated into the framework of MCM-4, the spherical structure distorted to elongated elliptical particles having particle diameter in the range of 400 nm and length in the range of 1  $\mu\text{m}$  (as shown in figure 4.5b, b'). There is a significant difference in the particle size, observed due to incorporation of iron atom to MCM-41 framework. Figure 4.6a, b displayed the low and high magnification HRTEM images of the mesoporous Fe-MCM-41. The images suggested that the prepared materials are mesoporous with less ordered in hexagonal arrays. Less ordered mesoporous

silicate frame work is observed due to incorporation of iron oxide nanoparticles inside the framework of MCM-41. The HRTEM result is in good agreement with the XRD result. The energy-dispersive spectroscopy (EDS) of Fe-MCM-41 is given in figure 4.6c. The presence of both Si and Fe atom is observed from the EDS spectrum.

**Figure 4.6** (a) Low and (b) high magnification HRTEM images of Fe-MCM-41 and (c) EDS spectrum of Fe-MCM-41

FTIR spectra of MCM-41 and Fe-MCM-41 are shown in figure 4.7. In the spectra of MCM-41, the absorption peak at  $3,200\text{--}3,650\text{ cm}^{-1}$  is due to hydroxyl group (OH), indicating the presence of water crystallization in the sample. The peak obtained at  $1630\text{--}1650\text{ cm}^{-1}$  is the characteristics of  $\text{SiO}_2$ . The two bands observed at  $1050$  and  $1250\text{ cm}^{-1}$  belonged to internal and external asymmetric Si-O-Si stretching frequencies. The peaks at  $955\text{--}965$  and  $795\text{--}810\text{ cm}^{-1}$  are due to Si-O stretching and symmetric Si-O stretching mode, respectively (Li et al., 2011; Kaya et al., 2010). It is observed that with the addition of Fe content, there is a slight red shift for the peaks around  $750$  to  $1250\text{ cm}^{-1}$  corresponding to the stretching vibration of the tetrahedral  $\text{TO}_4$  units ( $\text{T} = \text{Si}$  or  $\text{Fe}$ ); these shifts indicated that the heteroatoms were

incorporated into the frame-work of MCM-41 and M–O–Si bonds were formed. This is because the atomic weight of iron is larger than that of Si and the bond length of Fe–O were greater than that of Si–O, which led to a decrease in the vibration frequencies (Li et al., 2012).

**Figure 4.7** FTIR spectra of a) MCM-41, and b) Fe-MCM-41.

The surface area characterization of the prepared MCM-41 and Fe-MCM-41 was carried out by measuring their nitrogen adsorption/desorption isotherms. The N<sub>2</sub> adsorption–desorption isotherms and pore size distributions of both MCM-41 and Fe/MCM-41 are shown in Figure 4.8a and 4.8b, respectively. The samples exhibit pronounced steep condensation step for relative pressures 0.2 to 0.4 arising from condensation of nitrogen inside the primary mesopores which is a characteristic of typical type IV adsorption/desorption isotherm (Gaydhankar et al., 2006). The textural properties such as: inter-planar spacing ‘d’, unit cell parameters ‘a’, BET surface area, BJH pore diameters, total pore volume and wall thickness are given in table 4.2. The surface area of MCM-41 and Fe-MCM-41 were found to be 1266.3 and 880.4 m<sup>2</sup>/g, respectively. From the results it is observed that incorporation of iron on MCM-41 decreased surface area and pore diameter and increased the pore wall thickness and pore volume. Increasing of the pore wall thickness and pore volume may be attributed to the increasing micelles size due to the presence of the charged ions of iron salt. Whereas, decreasing of surface with incorporation of Fe atom in the MCM-41 can be explained in terms of pore blocking of MCM-41 matrix due to the presence of Fe<sub>2</sub>O<sub>3</sub> nanoparticles and their aggregates. This was likely to enhance adsorption and catalytic activity by facilitating the substrate transport and access to the confined mesopores (Huang et al., 2012). From the figure it is also found that both MCM-41 and Fe-MCM-41 exhibit narrow pore size distributions.

**Figure 4.8** Nitrogen adsorption/desorption isotherms of (a) MCM-41 and (b) Fe-MCM-41 and the relevant pore size distribution curves (inset).

**Table 4.2** Textural properties of prepared MCM-41 and Fe-MCM-41 materials

Sample	$d_{100}$ (nm)	<sup>b</sup> Unit cell $a_0$ (nm)	<sup>c</sup> Wall thickness (nm)	Surface area ( $m^2/g$ )	Pore size (nm)	Pore volume (cc/g)
MCM-41	3.27	3.77	0.64	1266.3	3.13	0.149
Fe-MCM-41	3.71	4.28	1.31	880.4	2.97	0.167

<sup>a</sup>Pore-size distribution and pore volume were determined from  $N_2$  adsorption isotherms at 77 K

<sup>b</sup> $a_0 = 2 \times d_{100}/3^{1/2}$

<sup>c</sup>The wall thickness was calculated as:  $a_0$ - pore size.

### 4.3.2. Adsorptive removal of methylene blue from aqueous media

#### 4.3.2.1. Effect of pH on removal of MB

pH is an important parameter for adsorption as it affects both the chemistry of the dye and the adsorbent materials and also plays an important role in the whole adsorption process and for determination of maximum absorption capacity (Mahapatra et al. 2013). Figure 4.9a shows the influence of the initial solution pH from 2 to 12 on the adsorption of MB onto MCM-41 and Fe-MCM-41. The pH of the test solutions was adjusted by using HCl and NaOH solutions. 0.05 g of each adsorbent was used in 20 ml of 100 mg/L MB solution at different pH value with 30 min agitation time. The adsorptive removal percentage of MB onto MCM-41 and Fe-MCM-41 was observed to be increased with increase in pH 2-9. From pH 9-12, there was no significant change in percentage of adsorption was observed. The results may be attributed to the following reasons. At lower pH, for cationic dye (MB) the lower adsorption values is probable due the presence of excess  $H^+$  ions competing with the cationic group on the dye for adsorption site. The increased adsorption at higher pH is mainly due to enhanced

association of the cationic dye with surface hydroxyl groups of MCM-41. It is related to the electrostatic force of attraction of the dye with the deprotonated hydroxyl group of adsorbents. Increase in the pH of the solution increases the electrostatic attraction between the positively charged dye and the surface of the adsorbent, which results in an increase in adsorption of MB dye. At high pH,  $\text{OH}^-$  on the surface of the adsorbent favors the adsorption of cationic dye molecules (Chen et al., 2010). Lee et al. (2007) and Monash and Pugazhenth (2010) have also reported a similar type of observation for the influence of pH on adsorption of methylene green and methylene blue (cationic dyes), respectively onto MCM-41. Therefore, further studies were carried out with pH 9 of dye solution. Application of higher pH in the wastewater treatment is also an advantage because of the following reason. Practically in wastewater treatment, high pH's also promote the precipitation of the toxic metal ions (if present in the waste water) as hydroxides. The metal hydroxide precipitates out from the solution and will not interfere with the competing ions of dye molecules. Therefore the dye molecules can be adsorbed more easily on the adsorbent surface.

**Figure 4.9** Effect of a) pH and b) amount of adsorbent (dose) on the removal of MB by MCM-41 and Fe-MCM-41.

#### 4.3.2.2. Effect of adsorbent dose on removal of MB

The study of adsorbent dosage provides knowledge of the effectiveness of the adsorbent and also shows the ability of dye to be adsorbed. The effect of adsorbent doses on the adsorption of MB onto MCM-41 and Fe-MCM-41 surface was studied at pH=9 using 20 ml of 100 mg/L MB solution for 30 min contact time. The result obtained is represented in figure 4.9b. From the figure it is observed that, with an increase in adsorption dose from 0.01 to 0.05 g, the percentage of removal of MB increased up to a maximum value of 99.9 % for Fe-MCM-41 and 94.5 % for MCM-41, respectively. This may be due to an increase in number of active sites of the adsorbent material with increasing amount of the adsorbent. After that further

increase in the amount of the adsorbent, no considerable change in the adsorption was observed. Hence, 0.05 g of each adsorbent was chosen as the optimum amount in future studies.

#### 4.3.2.3. *Kinetic Studies*

The effect of contact time on the adsorption of MB by MCM-41 and Fe-MCM-41 was studied for initial concentration of 100 mg/L of 20 ml Methylene blue solution by using 0.05 g adsorbent at pH 9. The contact time was varied from 10 to 60 minutes and the result obtained is shown in figure 4.10. From the figure 4.10a, it is observed that maximum adsorption occurred within 30 min of contact time; thereafter the rate of removal became rather slow i.e. the adsorption reaches steady state after 30 min for both the cases. We have studied the kinetics of adsorption of MB by MCM-41 and Fe-MCM-41 adsorbents and the experimental data obtained are applied to pseudo-first-order and pseudo-second-order kinetic model. The pseudo-first-order model is based on the hypothesis that the rate of change of solute uptake with time is directly proportional to difference in saturation concentration and the amount of solid uptake with time, while the pseudo-second-order model assumes that the adsorption rate is controlled by chemical adsorption through sharing or exchange of electrons between the adsorbent and adsorbate. The differential form of pseudo-first-order kinetic model is expressed as (Wang et al., 2014):

$$\ln(q_e - q_t) = \ln q_e - k_1 \cdot t \quad (4.2)$$

here,  $k_1$  is the rate constant of pseudo-first-order adsorption ( $\text{min}^{-1}$ ),  $q_e$  is the equilibrium adsorption capacity (mg/g), and  $q_t$  is the amount of dye adsorbed at time  $t$  (mg/g). The values of the pseudo-first-order rate constant  $k_1$  and  $q_e$  can be obtained from the slope and intercept of the straight line of the plot  $\ln(q_e - q_t)$  versus  $t$ .

The differential form of pseudo-second-order kinetic model is expressed as (Kumar and Rajesh, 2013):

$$\frac{t}{q_t} = \frac{1}{k_2 q_e^2} + \frac{t}{q_e} \quad (4.3)$$

here,  $k_2$  [g/(mg min)] is the rate constant of the pseudo-second-order equation and  $q_e$  and  $q_t$  are the amounts of solute adsorbed on the adsorbent at equilibrium and at time  $t$ , respectively. The values of  $q_e$  and  $k_2$  can be determined by the slope and intercept of the straight line of the plot  $t/q_t$  versus  $t$ , respectively. The parameters of the two kinetic models are given in table 4.3. From table, it is observed that the values of the correlation coefficients ( $r^2$ ) for the

pseudo-first-order model are very low, and the calculated  $q_e$  values ( $q_{e,cal}$ ) are quite different from the experimental values ( $q_{e,exp}$ ), indicating that the adsorption of MB onto both the MCM-41 and Fe-MCM-41 adsorbents cannot be applied to a pseudo-firstorder model. The correlation coefficients for the linear plots of pseudo-second-order model are higher ( $r^2 > 0.99$ ), and the theoretical calculated  $q_e$  values ( $q_{e,cal}$ ) are in good agreement with experimental  $q_e$  ( $q_{e,exp}$ ) values for both the MCM-41 and Fe-MCM-41 adsorbents. Therefore, the adsorption process of methylene blue on both the MCM-41 and Fe-MCM-41 is in good agreement to the pseudo-second order kinetic model. The pseudo-second-order plots for the adsorption of MB by MCM-41 and Fe-MCM-41 are shown in figure 4.10b and 4.10c, respectively.

**Table 4.3** Pseudo-first-order and Pseudo-second-order kinetic parameters for the removal of MB by MCM-41 and Fe-MCM-41

Adsorbent	$q_{e,exp}$ (mg/g)	Pseudo-first-order model			Pseudo-second-order model		
		$k_1$ ( $\text{min}^{-1}$ )	$q_{e,cal}$ (mg/g)	$r^2$	$k_2$ ( $\text{g mg}^{-1} \text{min}^{-1}$ )	$q_{e,cal}$ (mg/g)	$r^2$
MCM-41	38.15	0.0139	10.25	0.7183	0.0075	40.32	0.997
Fe-MCM-41	39.97	0.0653	16.27	0.7419	0.0086	42.19	0.998

**Figure 4.10** (a) Percentage removal of MB by MCM-41 and Fe-MCM-41 as a function of time (min), and Pseudo-second-order plot for removal of MB by (b) MCM-41 and (c) Fe-MCM-41.

#### 4.3.2.4. Adsorption isotherm

We have studied the adsorption isotherms to describe the interaction of molecules of adsorbate (dye) with adsorbent surface. The isotherm provides a relationship between the concentration of dye in solution and the amount of dye adsorbed on the adsorbent when both phases are in equilibrium. The analysis of the isotherm data is of great importance by fitting them to different isotherm models to optimize the adsorption system. Several adsorption isotherms models are available, but in the present study, we have followed the most widely used Langmuir and Freundlich isotherm models.

The Langmuir isotherm model assumes monolayer coverage of adsorbate on a homogeneous adsorbent surface. This model does not consider surface heterogeneity of the sorbent. It assumes that adsorption will take place only at specific site on the adsorbent. The Langmuir equation is given as (Nassar et al., 2011):

$$q_e = \frac{K_L q_{max} C_e}{1 + C_e K_L} \quad (4.4)$$

where  $K_L$  is the Langmuir constant related to the energy of adsorption,  $q_{max}$  is the maximum adsorption capacity corresponding to complete monolayer coverage ( $\text{mg g}^{-1}$ ), which depends upon the number of adsorption sites.

The Freundlich isotherm model describes the surface heterogeneity of the sorbent and considers multilayer adsorption with a heterogeneous energetic distribution of active sites, accompanied by interactions between adsorbed molecules. The Freundlich equation is given by (Nassar, 2010):

$$q_e = K_F C_e^{1/n} \quad (4.5)$$

where  $C_e$  is the equilibrium concentration ( $\text{mg L}^{-1}$ ),  $q_e$  is the amount adsorbed at equilibrium ( $\text{mg g}^{-1}$ ) and  $K_F$  and  $n$  are Freundlich constants, related to the extent of the adsorption and the degree of nonlinearity between solution concentration and adsorption, respectively.

The adsorption equilibrium data obtained from adsorption of MB by both MCM-41 and Fe-MCM-41 were non-linearly fitted to the Langmuir and Freundlich isotherms. The parameters and correlation coefficients calculated from the models are listed in table 4.4. It can be seen that the least-squares correlation coefficient ( $R^2$ ) value of the Langmuir model is significantly higher than that of the Freundlich model for both the cases of adsorbents, indicating that the Langmuir model should better describe the methylene blue adsorption on MCM-41 and Fe-MCM-41. The Langmuir and Freundlich adsorption isotherm plots for removal of MB by

MCM-41 and Fe-MCM-41 are given in figure 4.11a and 4.11b, respectively. This result indicates that the adsorption capacities of MCM-41 and Fe-MCM-41 for adsorption of MB are 149.5 and 194 mg g<sup>-1</sup>, respectively.

**Table 4.4** Langmuir and Freundlich Constants for the adsorption of MB.

Adsorbent	Langmuir isotherm model			Freundlich isotherm model		
	$q_{\max}$ (mg g <sup>-1</sup> )	$K_L$ (Lg <sup>-1</sup> )	$r_L^2$	$K_F$	$n$	$r_F^2$
MCM-41	149.5	0.056	0.988	27.57	2.96	0.95
Fe-MCM-41	194	0.387	0.957	73.65	3.66	0.915

**Figure 4.11** Non-linear fits of Langmuir and Freundlich isotherm models for removal of MB by (a) MCM-41 and (b) Fe-MCM-41.

#### 4.3.2.5. Adsorption mechanism

In MCM-41 the Si atoms carry -OH groups. Adsorption process is mainly dependent upon the affinity of the adsorbates towards H<sup>+</sup> and OH<sup>-</sup> ions of the adsorbents. Adsorbents surfaces possess different charges in solution with different pH values, causing electrostatic attraction or repulsion to the adsorbates. For cationic dyes, the adsorption of an adsorbent towards them increases with increasing pH, because of the electrostatic attraction. Here, at pH 9 or above the MCM-41 walls get negatively charged, which favored the adsorption of cationic MB dye. The adsorption capacity of Fe-MCM-41 towards the adsorption of methylene blue is higher than MCM-41. This may be due to presence of more negative sites (i.e. both O<sup>-</sup> and Fe<sup>-</sup>) on the wall of Fe-MCM-41, which causes more adsorption of methylene dye molecules (figure 4.12).

**Figure 4.12** Proposed mechanism for MB adsorption on MCM-41 and Fe-MCM-41.

#### 4.4. Conclusions

We have reported the synthesis of high surface area mesoporous MCM-41 and iron oxide impregnated MCM-41 nanomaterials by a facile wet chemical method. XRD and XPS studies suggested the presence of mixture of FeO and Fe<sub>2</sub>O<sub>3</sub> inside porous matrix of MCM-41 for Fe-MCM-41. HRTEM studies revealed the formation of mesoporous structure with less ordered in hexagonal arrays of Fe-MCM-41. Again, N<sub>2</sub> adsorption/desorption isotherm study confirm the formation of mesoporous materials with surface areas of 1266 and 880 m<sup>2</sup>/g for MCM-41 and Fe-MCM-41, respectively. The surface morphology of Fe-MCM-41 materials was found to be elliptical in shape having diameter in the range of 300-400 nm and length up to 1 micron. The prepared mesoporous nanomaterials were used as adsorbents for adsorptive removal of Methylene blue from aqueous media. It is observed that the adsorption isotherm data fit well with Langmuir model indicating that adsorption occurred by monolayer coverage. The kinetic study showed that the adsorption followed the pseudo-second-order kinetics model. It is also observed that the sorption performance of MCM-41 towards removal of methylene blue has been enhanced further by incorporation of iron oxide into mesoporous matrix. The maximum sorption capacity of prepared Fe-MCM-41 materials is found to be 194 mg g<sup>-1</sup> which is comparable to the recently reported adsorbents (polyaniline nanotubes base/silica composite, 10.31 mg g<sup>-1</sup> (Ayad et al., 2012), Ni-MCM-41, 157.48 mg g<sup>-1</sup> (Shu et al., 2015), nanoporous SBA-3, 285.7 mg g<sup>-1</sup> (Anbia and Hariri, 2010)).

## **CHAPTER-5**

### **IRON BASED MAGNESIUM OXIDE NANOMATERIALS FOR ADSORPTIVE REMOVAL AND PHOTOCATALYTIC DEGRADATION OF TOXIC DYES**

#### **PART A: MgO NANOSTRUCTURES: SYNTHESIS AND ADSORPTION STUDIES**

##### **5.1. Introduction**

Magnesium oxide (MgO) is a typical wide band gap (7.2 eV) semiconductor, which represents an important class of functional metal oxides with a broad range of properties. It has attracted considerable attention for its novel properties and large variety of applications in the field of catalyst, catalyst supports, refractory materials, paints, toxic waste remediation, optoelectronics, microelectronics, additive in heavy fuel oil, paint, gas separation, bactericides, insulator in industrial cables, crucibles and superconductors (Liu et al., 2014; Balamurugan et al., 2014; Sutradhar et al., 2011).

Nanostructured materials have high surface areas and a large fraction of atoms available for various applications. Nanostructured alkaline earth metal oxides, in particular MgO, are very favorable candidate materials for applications as adsorbents due to their specific affinity and high surface capacity. MgO nanomaterials have been explored as a nontoxic and environmentally friendly adsorbent to remove organic pollutants and toxic metal ions from water (Wang et al., 2014). Among the various techniques for removal of organic pollutants from waste-water, adsorption process has been proven as an effective removal method, due to its efficiency, simplicity, and applicability (Mittal et al., 2010). Hence, synthesis of MgO with high surface area is of great interest for adsorption applications (Hu et al. 2010; Nga et al. 2013).

Recently, enormous efforts have been made to synthesize MgO with enhanced surface area in varying morphologies such as rods, wires, belts, tubes, and so forth. Among various synthesis methods, chemical methods are the promising approaches due to their simplicity, cost-effective, high yield of final product and low reaction temperature (Sutradhar et al., 2011). Many researchers have adopted MgO and Mg(OH)<sub>2</sub> as an absorbent to remove toxic ions and organic pollutants from water. Gao et al. (2008) have synthesized MgO with various

morphologies such as nanoflakes, mesoporous microspheres composed of nanoflakes by adjusting the composition and phase structure of magnesium carbonate hydrate. They have applied the prepared MgO nanomaterials for adsorption of Cd(II), Pb(II), Cr(VI) ions and Orange G dye from waste water and found that the mesoporous MgO exhibited excellent absorption performance for both low and high valence heavy metal ions and organic pollutants in water. Venkatesha et al. (2012) have synthesized MgO nanoparticles by precipitation method and have studied their adsorption behaviour towards removal of Levafix fast red CA (LFR) and Indanthren blue BC (IB) from aqueous media. They have observed that the synthesized MgO nanoparticles regarded as an efficient adsorbent with maximum adsorption capacities of 92.16 mg/g and 86.50 mg/g for LFR and IB respectively. Tian et al. (2013) have synthesized porous hierarchical MgO by a facile and scaled-up method and reported that the MgO sample exhibited excellent adsorption properties with maximum adsorption capacity of 2409 mg g<sup>-1</sup> for removal of Congo red from aqueous solution. Yu et al. (2011) have synthesized flower-like and nest-like micro-/nanostructured MgO by a simple precipitation method and have studied their adsorption behavior for removal of As(III) and As(V) ions from water. They have reported that maximum uptake capacities of flower-like and nest-like MgO for As(III) are higher than 252.34 and 643.84 mg/g, while for As(V) it could reach 343.64 and 378.79 mg/g, respectively. Hu et al. (2010) have prepared MgO nanoplates by hydrothermal method and reported that the MgO nanoplates acted as efficient adsorbents for removal of Congo red and reactive brilliant red X3B dyes from water with maximum adsorption capacities of 303 and 278 mg g<sup>-1</sup>, respectively. Similarly, Cao et al. (2012) have synthesized flowerlike MgO nanomaterials with high surface area by a facile microwave-assisted solvothermal process and applied the nanomaterials for adsorption of Pb(II) and Cd(II) ions from aqueous solution. They have reported that the flowerlike MgO nanostructures showed superb adsorption properties for Pb(II) and Cd(II), with maximum uptake capacities of 1980 mg/g and 1500 mg/g, respectively.

In the current chapter, we have selected iron oxide based alkaline earth metal oxides nanomaterials, in particular nanosized magnesium oxide (MgO), because they are very promising materials for applications as adsorbent due to high surface reactivity and adsorption capacity compared to their commercial analogs and the simplicity of its production from abundant natural minerals (Mahmoud et al., 2013). The first part of this chapter describes the synthesis of Magnesium oxide nanomaterials with different morphologies. To study the adsorption capacity of MgO nanomaterials and their applications

towards adsorptive removal of range of organic dyes, we have selected both anionic Congo red (CR) and cationic Malachite green (MG) dyes in this work.

Herein, we have synthesized large scale MgO nanorods, hierarchical nanostructures and nanoflakes by chemical synthesis routs such as precipitation, reflux and hydrothermal methods, respectively. The synthesized MgO nanomaterials were used as adsorbents to remove both cationic Malachite green (MG) and anionic Congo red (CR) dyes from aqueous media. The adsorption experiments such as effects of materials type, adsorbent dose and initial concentration variation were explored in batch experiments.

## 5.2. Materials and methods

### 5.2.1. Materials used

The following chemicals were used for the synthesis of magnesium oxide nanostructures and dye adsorption experiments. Magnesium chloride ( $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ ), ammonium carbonate ( $(\text{NH}_4)_2\text{CO}_3$ ) and Malachite Green (oxalate) were purchased from Merck India pvt. Ltd. Congo red was purchased from Merck Germany pvt. Ltd. All the reagents used in the synthesis were of analytical grade and used as received without further purification.

### 5.2.2. Synthesis of MgO nanomaterials

Stoichiometric amounts of  $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$  and  $(\text{NH}_4)_2\text{CO}_3$  were dissolved separately in 100 ml each of double distilled water to form solution-A and B, respectively. Solution-B was added instantly to solution-A with vigorous stirring. The stirring was continued for 20 mins to obtain white colored homogeneous solution. Then we have followed three different routes to obtain MgO nanomaterials with different morphologies. The detailed synthesis procedure of MgO nanomaterials are schematically presented figure 5.1.

**Figure 5.1** Schematic representation of the synthesis of different MgO nanomaterials.

**Scheme 1:** The stirring was continued for 6 hrs and the white precipitate was filtered, washed with distilled water followed by ethanol and dried at 80 °C to form artinite. Then, the product was calcined at 400 °C for 3 hrs to form MgO nanorods (named as MgO-P).

**Scheme 2:** The solution was transferred into a round bottomed flask and refluxed for 6 hrs at 120 °C to form hydromagnesite precursor. The obtained precursor was filtered, washed and dried at 80 °C and finally calcined at 400 °C for 3 hrs to form hierarchical MgO nanostructures (named as MgO-R).

**Scheme 3:** The solution was transferred into a Teflon-lined autoclave followed by hydrothermal treatment for 6 hrs at 150 °C to form hydromagnesite precursor. Then the precursor was centrifuged, washed with distilled water and then by ethanol followed by drying at 80 °C and finally calcined at 400 °C for 3 hrs to form MgO nanoflakes (named as MgO-H).

### 5.2.3. Characterizations

The crystalline phases of the prepared nanomaterials were investigated by X-ray powder diffraction (XRD, Rigaku Ultima-IV) using Cu K $\alpha$  radiation. The field emission scanning electron microscopy (Nova Nano SEM/FEI, 20 kV) was performed to observe the shapes and morphologies. Fourier transforms infrared (FTIR) spectra were measured on Perkin-Elmer FTIR (Spectrum RX-I) spectrometric analyzer. N<sub>2</sub> adsorption–desorption isotherm was determined on a Quantachrome (Autosorb-iQ) physisorption apparatus.

### 5.2.4. Adsorption studies of Malachite green (MG) and Congo red (CR) dyes

The different MgO nanomaterials prepared were used as adsorbents and their adsorption efficiencies were investigated by using Malachite green (MG) and Congo red (CR) dyes from aqueous media. Initially a stock solution of 1 g of Malachite green and Congo red was dissolved in 1000 ml of double distilled water. Batch adsorption experiments were conducted in order to investigate the effects of materials type (MgO-P, MgO-R and MgO-H), solution pH (3-8), adsorbent dose (0.003-0.01 g), initial dye concentration (100-500 mg/l) and contact time (15-90 min) for adsorption of MG and CR dyes. The pH of the dye solutions was adjusted using 0.1M HCl and 0.1M NH<sub>4</sub>OH solution. After the batch adsorption experiment, the residual concentrations of the dye solutions was measured by using Shimadzu UV-2450 spectrometer at  $\lambda_{\text{max}}$ =615 for MG and  $\lambda_{\text{max}}$ =498 for CR. All the batch adsorption experiments were carried out at room temperature. All the adsorption experiments were carried out three times in replicates and the mean data obtained were taken in results and discussion section.

### 5.3. Results and Discussion

**5.3.1. Surface Morphology and microstructure:** Figure 5.2(a, a') represents the SEM and FESEM images of MgO nanomaterials synthesized by precipitation method. The images suggest the formation of smooth and randomly arranged rod shaped nanomaterials with average diameters around 400-500 nm. The SEM images of MgO nanomaterials synthesized by reflux method are shown in figure 5.2(b, b'). The low-magnification SEM image (figure 5.2(b)) demonstrates the formation of uniform flower-like hierarchical nanostructures. The high-magnification FESEM image (figure 5.2(b')) visualizes that the hierarchical nanostructures contains plates with thickness around 100-200 nm. Figure 5.2(c, c') represents the SEM images of MgO nanomaterials synthesized by hydrothermal method. The images indicate the formation of flakes like nanomaterials with diameter around 300-500 nm. The energy-dispersive spectroscopy (EDS) spectrum of hierarchical MgO nanostructures (figure 5.2(d)) demonstrates the presence of O and Mg elements without any impurities.

**5.3.2. XRD analysis:** Figure 5.3a shows the XRD patterns of as-synthesized and calcined nanorods obtained by precipitation method. The as-synthesized sample contains characteristics peaks of artinite (Magnesium carbonate hydroxide hydrate,  $\text{Mg}_2\text{CO}_3(\text{OH})_2(\text{H}_2\text{O})_3$ ) with monoclinic crystal structure according to JCPDS file number 70-0591. After calcination at 400 °C for 4 hrs the artinite nanorods were converted to MgO nanorods. The patterns can be indexed to cubic crystalline structure according to JCPDS file number 78-0430. Figure 5.3b shows the XRD patterns of as-synthesized and calcined hierarchical nanostructures obtained by reflux method. The as-synthesized samples contain mixture of monoclinic and orthorhombic hydromagnesite crystal structures according to JCPDS file number 25-0513 and 70-1177, respectively. After calcination at 400 °C for 4 hrs, the hydromagnesite was converted to MgO and can be indexed to cubic crystalline structure according to JCPDS file number 78-0430. Again, the XRD patterns of as-synthesized and calcined nanoflakes prepared by hydrothermal method are shown in figure 5.3c. The as-synthesized nanoflakes contain mixture of monoclinic and orthorhombic hydromagnesite crystal structures according to JCPDS file number 25-0513 and 70-1177, respectively and the calcined nanoflakes contain characteristics peaks of cubic crystalline MgO according to JCPDS file number 78-0430. The XRD patterns reveal the well crystalline nature of the samples without presence of any impurities.

**Figure 5.2** Low and high magnification SEM and FESEM images of (a, a') MgO nanorods, (b, b') hierarchical MgO nanostructures, (c, c') MgO nanoflakes and (d) EDS of hierarchical MgO nanostructures.

**Figure 5.3** XRD patterns of (a) Artinite and MgO nanorods prepared by precipitation method, (b) hierarchical Hydromagnesite and MgO nanostructures prepared by reflux method, (c) Hydromagnesite and MgO nanoflakes prepared by hydrothermal method, (d) FTIR patterns, (e) N<sub>2</sub> adsorption/desorption isotherms and (f) pore-size distribution of MgO nanorods, hierarchical nanostructure and nanoflakes.

**5.3.3. FTIR analysis:** The FTIR patterns of prepared MgO nanomaterials are presented in figure 5.3d. Peaks at  $3700\text{--}3300\text{ cm}^{-1}$  are corresponding to the O–H stretching mode of hydroxyl groups present on the surface due to moisture. A broad band at  $1460\text{--}1400\text{ cm}^{-1}$  in each pattern corresponds to Mg–O stretching vibrations. Peaks at  $850\text{--}900\text{ cm}^{-1}$  corresponds to  $\nu_1$  and  $\nu_2$  stretching vibrations of metal oxygen bond. The major peaks in the range of  $440\text{--}690\text{ cm}^{-1}$  are due to Mg–O stretching vibrations.

**5.3.4. Surface area and porosity analysis:** The  $\text{N}_2$  adsorption-desorption isotherm and pore size distribution are shown in figure 5.3e, f. From figure 5.3e, it is observed that the BET surface area of MgO nanorods, hierarchical nanostructures and nanoflakes are 48.45, 147.5 and  $110.9\text{ m}^2/\text{g}$ , respectively. From BJH pore size distribution curve (figure 5.3f), the pore diameters of MgO nanorods, hierarchical nanostructures and nanoflakes are found to be 3.8, 4.9 and 6.15 nm.

### **5.3.5 Removal of Malachite green and Congo red from aqueous media**

**Effect of materials types on adsorption:** The MgO nanorods, hierarchical nanostructures and nanoflakes were applied as adsorbents to remove Malachite green (MG) and Congo red (CR) from aqueous solutions. 0.01 g of each adsorbent was added to 20 ml of  $100\text{ mg L}^{-1}$  solution of MG and CR separately and adsorption was carried out for 60 min. From figure 5.4a, it is observed that the percentage of removal of MG by MgO nanorods, hierarchical nanostructures and nanoflakes are 95.1, 99.98 and 97.42 %, respectively and percentage of removal of CR by MgO nanorods, hierarchical nanostructures and nanoflakes are 86.28, 99.94 and 92.68 %, respectively. The hierarchical MgO nanostructure shows better removal capacity for both the dyes than other two adsorbents. It may be due to its high surface area and hierarchical structure, which can provide more available active adsorption sites and efficient transport pathways. Hence, we have chosen hierarchical MgO nanostructure for further adsorption study by varying the pH, amount of dose, contact time and dye concentration.

**Effect of pH on Adsorption:** The effect of pH is an important controlling parameter on the dye adsorption capacity, which affects both aqueous chemistry and surface binding sites of the adsorbents. Figure 5.4b shows the percentage adsorption of 20 mL of  $100\text{ mg L}^{-1}$  MG and CR dye solutions with  $\text{pH} = 3\text{--}8$ . The natural pH of  $100\text{ mg L}^{-1}$  Malachite green is 5.6–6. Below pH 3 (acidic range) the dye becomes colourless and above pH 8 the dye also becomes purely colourless, so this experiment was done in pH range of 3–8. At pH 3 the percentage

removal of MG was more than 95 % and it increased with the increase in the pH upto 6 after that the adsorption percentage was remains constant. The result can be explained by the fact that at low pH, the concentration of  $H^+$  ion is high causing a competition for the adsorption sites of the MgO surface between the  $H^+$  ions and cationic malachite green dye molecules. When the pH increase the formation of electric double layer changes its polarity and consequently the dye uptake increases (Mittal, 2006; Gupta et al., 2004). After the pH value 6, the uptake of MG dye was slightly increased and remained virtually unchanged. This result could be attributed due to the fact that, with increase in pH from 6 to 8, the concentration of competitive  $H^+$  ions in the solution decreases, hence the adsorption of positively charged MG dye onto MgO surface surface increases. The natural pH of 100 mg  $L^{-1}$  Congo red dye is pH of 7.6. It was found that the dye solution becomes dark blue when the pH was lowered to 3 and deep red when the pH was above 10-12. Therefore, in this study, the pH of the solution was maintained in between 3-8. It is observed from the figure 5.4b, that the adsorption increased with increasing pH from 3 to 7 and after that decreased. The removal of CR increased in pH range 3-7 due to the electrostatic attraction between the anionic dye molecules (negatively charged) and MgO surface (positively charged;  $pH_{zpc}$  12.4). However, the reduction of CR removal percent at higher pH might be explained by the formation of  $OH^-$  and subsequent competition with the CR molecules for adsorption site (Moussavi and Mahmoudi, 2009). Hence for all the future study we have chosen the natural pH of both the dye solutions.

**Effect of adsorbent dose:** Figure 5.4c shows the variation of amount of adsorbent dosage with percentage removal of MG and CR for 20 mL each of 100  $mgL^{-1}$  dyes with 60 mins contact time. It is observed that, with increase in amount adsorbent dose from 0.003 g to 0.01 g, the percentage of adsorption increases: which may be due to increase in the active sites of the adsorbent. Further increase in the amount of the adsorbent does not bring any considerable change in the adsorption. The percentages removal of MG and CR are found to more than 99 % each for 0.01 g of adsorbent, hence we have chosen 0.01 g as the optimum amount for further study.

**Figure 5.4** Effect of (a) material types, (b) pH and (c) amount of dose on the adsorption of MG and CR.

**Adsorption Kinetics:** In order to understand the dynamics of adsorption process in terms of the order of reaction and rate constant, the kinetics study for the adsorption of MG and CR dye on hierarchical MgO nanostructure has been carried out. The kinetics of adsorption of Malachite green and Congo red dye on the MgO hierarchical nanostructure is well described by using the pseudo-second-order kinetics model.

The pseudo second order model is represented by the following equation (Chen et al., 2015):

$$\frac{t}{q} = \frac{1}{k_2 q_e^2} + \frac{t}{q_e} \quad (5.1)$$

The equilibrium adsorption capacity ( $q_e$ ) and the second-order rate constants  $k_2$  ( $\text{g}^{-1} \text{mg min}$ ) can be determined experimentally from the slope and intercept of plot of  $t/q$  versus  $t$ . The best-fit values of  $h$ ,  $q_e$  and  $k_2$  along with correlation coefficients of the pseudo-second-order model for the three adsorbents are shown in table 5.1, and the pseudo-second-order plots of adsorption of Malachite green and Congo red are given in figure 5.5.

**Table 5.1** Pseudo-second-order kinetic parameters for the removal of MG and CR

Adsorbate	$K_2$ (g mg <sup>-1</sup> min <sup>-1</sup> )	$q_e$ (mg/g) (Calculated)	$q_e$ (mg/g) (Experimental)	$r^2$
Malachite green	0.0277	200	199.97	0.999
Congo red	0.0053	204.08	199.98	0.999

**Figure 5.5** Pseudo-second-order plot for removal of (a) Malachite green and (b) Congo red

The values of predicted equilibrium adsorption capacities ( $q_e$ ) showed good agreement with the experimental equilibrium uptake values. Similarly, correlation coefficients are always greater than 0.99, which also explains the good fit of the model.

**Adsorption isotherm:** The equilibrium adsorption isotherm is essential in describing the interaction between adsorbate and adsorbent, and to evaluate the efficacy of the prepared adsorbent for the design of an appropriate adsorption system. Several adsorption isotherms models are available. In the present study; we have followed the most widely used Langmuir and Freundlich isotherm models. Effect of initial dye concentration was studied with varying concentration ranging from 100 to 500 mg L<sup>-1</sup>. Then, Langmuir and Freundlich isotherm model were used to determine the adsorption capacities of hierarchical MgO nanostructure towards removal of MG and CR.

The Langmuir equation is given as (Zhu et al., 2012):

$$q_e = \frac{K_L q_{\max} C_e}{1 + C_e K_L} \quad (5.2)$$

where  $K_L$  is the Langmuir constant related to the energy of adsorption,  $q_{\max}$  is the maximum adsorption capacity corresponding to complete monolayer coverage (mg g<sup>-1</sup>), which depends upon the number of adsorption sites.

The Freundlich equation is given by:

$$q_e = K_F C_e^{1/n} \quad (5.3)$$

where  $C_e$  is the equilibrium concentration ( $\text{mg L}^{-1}$ ),  $q_e$  is the amount adsorbed at equilibrium ( $\text{mg g}^{-1}$ ) and  $K_F$  and  $n$  are Freundlich constants, related to the extent of the adsorption and the degree of nonlinearity between solution concentration and adsorption, respectively. The isotherm constants and correlation coefficients were calculated and listed in table 5.2. It is observed that the adsorptions of both MG and CR are better fitted to the Langmuir model with maximum adsorption capacities of 1205.23 and 1050.81  $\text{mg/g}$ , respectively.

**Table 5.2** Adsorption isotherm constants for Malachite green and Congo red

Adsorbate	Langmuir			Freundlich		
	$q_{\text{max}}$ ( $\text{mg g}^{-1}$ )	$K_L$	$R^2$	$K_F$	$n$	$R^2$
Malachite green	1205.23	12.69	0.999	1506.61	2.52	0.932
Congo red	1050.81	1.21	0.973	536.02	3.29	0.934

## 5.4. Conclusions

MgO nanomaterials were successfully synthesized by three different wet chemical methods such as: precipitation, reflux and hydrothermal methods. SEM and FESEM images suggested the formation of nanomaterials with three different morphologies i.e. nanorods, hierarchical nanostructures and nanoflakes by precipitation, reflux and hydrothermal methods, respectively. XRD results revealed the crystalline nature of the prepared MgO nanomaterials. FTIR result also indicates the formation of Mg-O bands. The three different MgO nanomaterials prepared were used as adsorbents towards the removal of Malachite green and Congo red from aqueous solution. The hierarchical MgO nanostructures showed excellent dye adsorption performance with maximum adsorption capacities of 1205 and 1051  $\text{mg/g}$  for Malachite green and Congo red, respectively.

## **PART B: $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3$ HETEROSTRUCTURED NANOMATERIALS FOR PHOTOCATALYTIC DEGRADATION OF METHYLENE BLUE DYE**

### **5.5. Introduction**

In the first part of this chapter, we have described the synthesis of MgO nanomaterials with different morphologies by precipitation, reflux and hydrothermal methods, respectively. The MgO nanomaterials have been used as adsorbents for removal of Congo red and Malachite green dye from aqueous media. In this part, we have presented on the synthesis of Iron based magnesium oxide composites nanomaterials following the same synthetic methods. After studying the adsorption properties of iron oxide based composite materials, we intend to study complete decomposition of organic pollutants. Since adsorption process transfer on pollutant from one medium to another, hence photocatalytic process has been chosen for complete degradation of organic pollutants.

Among spinel ferrites, ecofriendly magnesium ferrite ( $\text{MgFe}_2\text{O}_4$ ) nanostructures have shown the attention of researchers in different fields such as magnetic and catalytic materials, gas sensors and photocatalytic applications (Shen et al., 2013; Mathew et al., 2007). The perovskite or spinel related oxide photocatalysts exhibit enhanced efficiency due to the available extra catalytic sites by virtue of their crystal lattices (Dom et al., 2011).  $\text{MgFe}_2\text{O}_4$  can absorb visible light due to its small bandgap (2 eV) and is not sensitive to photoanodic corrosion and hence, this material is considered a potential solar energy material for photoelectric conversion (Zhang et al., 2011). Instead of using a single metal oxide, coupling with other metal oxide forming a heterostructure has been found to suppress the recombination of electron-hole pairs, and thus leading to remarkably enhanced photocatalytic property (Barakat et a., 2013).

It is known that both  $\text{MgFe}_2\text{O}_4$  and  $\alpha\text{-Fe}_2\text{O}_3$  are n-type semiconductors with small bandgap (2-2.2 eV). When  $\text{MgFe}_2\text{O}_4$  and  $\alpha\text{-Fe}_2\text{O}_3$  form heterojunction, the photogenerated electrons and holes are separated efficiently, leading to enhancement in photocatalytic activity. Recently, our group has synthesized large scale MgO nanomaterials with different morphologies with excellent adsorption property by facile chemical synthesis routes (described in chapter-5, Part-A). In this present work, we have synthesized iron based magnesium oxides,  $\text{MgFe}_2\text{O}_4$  and  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3$  composite nanostructures. The synthesized nanomaterials have been used for photocatalytic degradation of methylene blue under solar

light irradiation. Methylene blue dye is one of the hazardous organic dyes which exist in wastewater and causes serious environmental problem. The photocatalytic degradation of MB dye by  $\text{Fe}_2\text{O}_3$  and  $\text{MgFe}_2\text{O}_4$  nanomaterials has been reported recently (Zhang et al., 2012; Liu et al., 2011; Kang et al., 2011; Shahid et al., 2013; Shakir et al., 2016). Therefore, in order to study the improve photocatalytic performance of the prepared mixed  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3$  composite nanostructures; we have selected MB as the challenging dye.

## 5.6. Materials and Methods

### 5.6.1. Materials used

The following chemicals were used for the synthesis of magnesium oxide nanostructures and dye adsorption study. Magnesium chloride ( $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ ) from Merck India private limited, Ammonium carbonate ( $(\text{NH}_4)_2\text{CO}_3$ ) from Merck India private limited, Ferrous chloride ( $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ ) from Merck Germany pvt. Ltd. and Methylene blue from Merck India pvt. ltd. All the reagents used in the synthesis were of analytical grade and used as received without further purification.

### 5.6.2. Synthesis procedure

2.03 g of  $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$  and 1.99 g of  $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$  was dissolved in 100 mL of distilled water to form solution-A. 6.24 g of  $(\text{NH}_4)_2\text{CO}_3$  were dissolved in 100 mL of distilled water to form solution- B. Solution-B was added instantly to solution-A with vigorous stirring. The stirring was continued for 20 min to obtained homogeneous solution. Then we have followed three different synthetic routes. The detailed synthesis procedure is schematically presented in figure 5.6.

**Figure 5.6** Schematic representation of the synthesis of different  $\text{MgFe}_2\text{O}_4$  nanomaterials

**Scheme 1:** The stirring was continued for 6 h and the precipitate was filtered, washed, dried and calcined at 600° C for 3h to form MgFe<sub>2</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub> nanocomposite (named as MgFe<sub>2</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub>-P). **Scheme 2:** The solution was refluxed for 6h at 120° C and then the precipitate was filtered, washed, dried and calcined at 600° C for 3h to form to form MgFe<sub>2</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub> nanocomposite (named as MgFe<sub>2</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub>-R). **Scheme 3:** The solution was transferred into a Teflon-lined autoclave followed by hydrothermal treatment for 6h at 150° C and then the precipitate was washed, dried and calcined at 600° C for 3h to form MgFe<sub>2</sub>O<sub>4</sub> nanoparticles (named as MgFe<sub>2</sub>O<sub>4</sub>-H).

**5.6.3. Characterization techniques:** The crystalline phases of the synthesized nanomaterials were investigated by X-ray powder diffraction (XRD, Rigaku Ultima-IV). The field emission scanning electron microscopy (Nova Nano SEM/FEI, 20 kV) was performed to observe the shapes and morphologies. Fourier transforms infrared (FTIR) spectra were measured on Perkin-Elmer FTIR (Spectrum RX-I) spectrometer. N<sub>2</sub> adsorption-desorption isotherm was done on a Quantachrome (Autosorb-iQ) apparatus. Methylene blue (MB) photodegradation experiments were carried out under solar light irradiation. All the experiments were performed at the location of 22°15'N 84°54'E during the months of May and June (sunny days), from 09.00 AM to 11:00 A. M., when the average solar intensity was found to be 1.0 kW m<sup>-2</sup> with minimum fluctuation. Prior to photoreaction the aqueous mixture was stirred in dark for 1h to reach adsorption-desorption equilibrium. During photoreaction 3 mL of aliquot was drawn at regular time interval and centrifuged for (MB, λ<sub>max</sub>=664 nm) absorbance analysis by UV-Vis spectrometer. The photocatalytic efficiency was calculated according to the following equation (Tao et al., 2013):

$$\text{Efficiency (\%)} = 100 \times \left( \frac{C_0 - C_t}{C_0} \right) \% \quad (5.4)$$

where C<sub>0</sub> and C<sub>t</sub> were the concentrations of MB at reaction time 0 and t, respectively.

## 5.7. Results and discussion

**5.7.1 XRD analysis:** Figure 5.7a shows the XRD pattern of MgFe<sub>2</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub> nanomaterials obtained by precipitation method. The pattern contains two sets of diffraction peaks, which are ascribed to cubic MgFe<sub>2</sub>O<sub>4</sub> according to JCPDF No: 73-1720 and rhombohedral α-Fe<sub>2</sub>O<sub>3</sub> according to JCPDF No: 72-0469 to form MgFe<sub>2</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub> composite structures. Figure 5.7b shows the XRD pattern of nanoparticles obtained by reflux method. The pattern also contains diffraction peaks of cubic MgFe<sub>2</sub>O<sub>4</sub> according to JCPDF No: 73-1720 and rhombohedral α-

Fe<sub>2</sub>O<sub>3</sub> according to JCPDF No: 72-0469 to form MgFe<sub>2</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub> composite structures. But in case of nanoparticles obtained by hydrothermal method, the XRD pattern (figure 5.7c) contains only the diffraction peaks of cubic MgFe<sub>2</sub>O<sub>4</sub> according to JCPDF No: 73-1720.

**Figure 5.7** XRD patterns of (a) MgFe<sub>2</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub>-P, (b) MgFe<sub>2</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub>-R and (c) MgFe<sub>2</sub>O<sub>4</sub>-H.

**5.7.2. FTIR analysis:** Figure 5.8 shows the FTIR spectra of MgFe<sub>2</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub>-P, MgFe<sub>2</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub>-R and MgFe<sub>2</sub>O<sub>4</sub>-H nanomaterials. The spectrum of MgFe<sub>2</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub>-P shows two persistent absorption bands of metal-oxygen bond corresponding to the vibration of tetrahedral and octahedral complexes at  $\nu_1=573\text{ cm}^{-1}$  and  $\nu_2=481\text{ cm}^{-1}$ , respectively. Similarly, MgFe<sub>2</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub>-R shows two absorption bands of metal-oxygen bond corresponding to vibration of tetrahedral and octahedral complexes at  $\nu_1=578\text{ cm}^{-1}$  and  $\nu_2=479\text{ cm}^{-1}$ , respectively. Again, the FTIR spectra of MgFe<sub>2</sub>O<sub>4</sub>-H (MgFe<sub>2</sub>O<sub>4</sub> phase) shows adsorption bands of metal-oxygen bond corresponding to vibration of tetrahedral and octahedral complexes at  $\nu_1=567\text{ cm}^{-1}$  and  $\nu_2=436\text{ cm}^{-1}$ , respectively. These are the evidence of formation of spinel ferrite structure. It is observed that the values of  $\nu_1$  and  $\nu_2$  of MgFe<sub>2</sub>O<sub>4</sub>-Fe<sub>2</sub>O<sub>3</sub> composites are increased compared with single MgFe<sub>2</sub>O<sub>4</sub>. This is due to the redistribution or inversion of cations among A- and B-site of MgFe<sub>2</sub>O<sub>4</sub> after the incorporation of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> (Shen et al., 2012).

**Figure 5.8** FTIR patterns of  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}$ ,  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-R}$  and  $\text{MgFe}_2\text{O}_4\text{-H}$ .

**5.7.3. Surface area and porosity analysis:** The  $\text{N}_2$  adsorption-desorption isotherm and pore size distribution are shown in Figure 5.9. From figure 5.9a, it is observed that the BET surface area of  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}$ ,  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-R}$  and  $\text{MgFe}_2\text{O}_4\text{-H}$  are 67, 36 and 50  $\text{m}^2/\text{g}$ , respectively. From BJH curve (figure 5.9b), the corresponding pore diameters are found to be 6.5, 5.6 and 4.8 nm.

**Figure 5.9** (a)  $\text{N}_2$  adsorption-desorption isotherms and (b) pore-size distribution of  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}$ ,  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-R}$  and  $\text{MgFe}_2\text{O}_4\text{-H}$ .

**5.7.4. Surface Morphology and microstructure:** Figure 5.10a, a' represents the FESEM images of  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3$  nanocomposites synthesized by precipitation method. The images suggest the formation of very smooth and fine spherical nanoparticles with average diameters around 20-40 nm. The FESEM images of  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3$  nanocomposites synthesized by reflux method are shown in figure 5.10b, b'. The low-magnified FESEM image (figure 5.10b) demonstrates the formation of both uniform microspheres and flower-like hierarchical nanostructures. The high-magnified FESEM image (figure 5.10b') represents that the

hierarchical nanostructures contains plate like morphology with thickness around 100-200 nm. Figure 5.10c, c' represents the FESEM images of  $\text{MgFe}_2\text{O}_4$  nanomaterials synthesized by hydrothermal method. The images indicate the formation of irregular shaped nanoparticles with diameter around 60-100 nm. The energy-dispersive x-ray spectroscopy (EDS) spectrum of  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3$  nanocomposites synthesized by precipitation method (Figure 5.10d) demonstrates the presence of O, Fe and Mg elements without any impurities.

**Figure 5.10** Low and high magnification FESEM images of (a, a')  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}$ , (b, b')  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-R}$ , (c, c')  $\text{MgFe}_2\text{O}_4\text{-H}$  and (d) EDS of  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}$ .

**5.7.5. Effect of types of photocatalysts:** The effect of photocatalyst types on degradation of MB was evaluated by adding 0.1 g each photocatalyst powder into 100 mL of 10 mg/L MB solution. From figure 5.11, it is observed that 99.9% dye degradation occurred within 120 min of reaction time using  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}$  photocatalyst. For  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-R}$ , around 89.1 and 93.8% dye degradation occurred within 120 and 150 min of reaction time, respectively. Similarly, for  $\text{MgFe}_2\text{O}_4\text{-H}$ , around 93.2 and 96.7% dye degradation occurred within 120 and 150 min of reaction time, respectively. The  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}$  photocatalyst shows better degradation capacity than other two photocatalysts. It may be due to the combined effects of high surface area (very smooth and smallest nanoparticles) and heterojunction nanostructure. In case of  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-R}$ , although it possess heterojunction nanostructure but due to less surface area and higher particle size than  $\text{MgFe}_2\text{O}_4\text{-H}$ , its photocatalytic activity is comparatively lesser than  $\text{MgFe}_2\text{O}_4\text{-H}$ . We have chosen  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}$  composite nanostructure for further photocatalytic study by varying initial dye concentration.

**Figure 5.11** Percentage of degradation of 10 mg/L MB using the three catalysts.

**5.7.6. Effect of initial concentration of MB:** The effect of initial concentration of MB dye on degradation was examined using 100 mL of 5-25 mg/L of MB using 0.1 g of  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}$  photocatalyst for 120 min irradiation time. It is observed from figure 5.12 that the degradation efficiency was gradually decreased with increase in dye concentration and around 97% degradation was occurred within 120 min for 25 mg/L MB. The primary factor

controlling the degradation of MB is the formation of hydroxyl radicals on catalyst surface and interaction of such radicals with dye species. With increasing initial concentration, much more dye molecules are adsorbed on catalyst surface, and hence the generation of hydroxyl radicals would be reduced. As a result, the photodegradation efficiency decreased. Again, due to a high concentration of dye a shielding effect for light passing into solution is attained, which reduced the absorption of photons by catalyst, and thus the hydroxyl radicals formed on catalyst surface would decrease (Harraza et al., 2014).

**Figure 5.12** Percentage of degradation of 5-25 mg/L MB using  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}$ .

**5.7.7. Kinetics study:** The apparent rate constant ( $k_{app}$ ) has been chosen as the basic kinetics parameter for all the photocatalytic reaction. The  $k_{app}$  arises from the Langmuir–Hinshelwood first-order kinetics equation as (Muthirulan et al., 2013):

$$\ln\left(\frac{C_0}{C_t}\right) = kKt = k_{app}t \quad (5.5)$$

where  $k$  is the reaction rate constant ( $\text{min}^{-1}$ ),  $K$  is the adsorption coefficient of dye on a catalyst particle ( $\text{L mol}^{-1}$ ) and  $K_{app}$  is the apparent rate constant. Figure 5.13a, b shows the graph of  $\ln(C_0/C_t)$  vs  $t$  for various photocatalysts and various concentrations. The apparent rate constants, % degradation and correlation coefficients for all photoreactions are given in table 5.3. The plots show a linear relationship with good correlation coefficient ( $R^2 > 0.947$ ), indicating that the MB degradation is best fit to the above kinetic model.

**Figure 5.13** Pseudo-first-order kinetics of (a) the three catalysts for 10 mg/L MB, (b)  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}$  for 5-25 mg/L MB.

**Table 5.3** Percentage of degradation and pseudo-first-order kinetic parameters of MB dye

Photocatalysts/MB concentration (mg/L)	Degradation (%)	$K_{\text{app}}$ ( $\text{min}^{-1}$ )	$R^2$
$\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}/10$	99.88	0.052	0.967
$\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-R}/10$	89.15	0.018	0.989
$\text{MgFe}_2\text{O}_4\text{-H}/10$	93.23	0.022	0.991
$\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}/5$	99.89	0.048	0.947
$\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}/15$	99.30	0.036	0.968
$\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}/20$	98.80	0.034	0.977
$\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}/25$	96.92	0.027	0.986

**5.7.8. Reusability study:** The reusability and stability of photocatalysts is an important issue for practical applications. We have repeated the degradation of 10 mg/L MB solution four times using  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}$  and the result is shown in figure 5.14. As can be seen, the repeatability of the entire process and the final result of degradation of MB are very good, which further demonstrate the excellent efficiency of the photocatalyst.

**Figure 5.14** Four recycling runs of  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}$  for MB degradations.

**Photocatalytic mechanism:** Heterojunction is the main reason of enhanced photocatalytic activity of  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}$  nanocomposite. The photocatalytic processes are based on electron hole pairs generated from band gap excitation. The photoinduced electron-hole pairs migrate on the surface of the photocatalyst to react with the adsorbed reactants in the desired process, or undergo an undesired recombination. Therefore, the generation and separation of the electron-hole pairs are the key factors to influence a photocatalytic reaction. In order to explain the possible transfer mechanism of photogenerated charge carriers in  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3\text{-P}$ , an energy band diagram of  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3$  has been proposed in figure 5.15. When the  $\text{MgFe}_2\text{O}_4$  is excited by solar light with photon energy higher than its band gap, the electrons in the valence band (VB) move to the conduction band (CB) generating equal amounts of holes in VB. The photogenerated electrons are migrated from CB of  $\text{MgFe}_2\text{O}_4$  to CB of  $\alpha\text{-Fe}_2\text{O}_3$  forming different valence bond edges. Which inhibits electron-hole recombination: as a result the electron-hole pairs react with the adsorbed dye molecules.

**Figure 5.15** Proposed mechanism of photo-reaction.

## 5.8. Conclusions

We have synthesized  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3$  composite nanostructures by precipitation and reflux methods and  $\text{MgFe}_2\text{O}_4$  nanostructure by hydrothermal method. XRD suggests the well crystalline nature of the nanomaterials with appropriate phase. FESEM images suggest that the  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3$  nanocomposites prepared by precipitation method contains very smooth nanoparticles with average diameters around 20-40 nm. However, the  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3$  nanocomposite prepared by reflux method contains both uniform microspheres and flower-like hierarchical nanostructures. The  $\text{MgFe}_2\text{O}_4$  nanomaterials synthesized by hydrothermal method contains irregular shaped nanoparticles with diameter around 60-100 nm. These prepared nanomaterials were used as photocatalysts for degradation of Methylene blue under solar light irradiation. It was observed that the  $\text{MgFe}_2\text{O}_4\text{-Fe}_2\text{O}_3$  nanocomposites prepared by precipitation method shows enhanced photocatalytic activity compared to the other prepared photocatalysts.

## CHAPTER-6

### ONE-DIMENSIONAL $\text{Fe}_2\text{O}_3$ -CuO NANOCOMPOSITES: SYNTHESIS, CHARACTERIZATION AND PHOTOCATALYTIC DEGRADATION OF METHYL ORANGE

#### 6.1. Introduction

Metal oxide based semiconductor photocatalysis is considered as one of the most promising green technologies for environmental remediation due to its potential utilization of solar energy for purification of water and air (Xie et al., 2014; Yuan et al., 2014; Zhao et al., 2015; Lv et al., 2014; Wang et al., 2015). It is the facile, cheap and non-toxic natural light-induced catalytic method for decontamination of inorganic and organic pollutants from waste water. The process involves the complete mineralization of the contaminant molecules into carbon dioxide, water and mineral acids. The contaminant molecules reduced through redox reactions and include generation of electron-hole pairs on the surface of a metal oxide photocatalyst by the absorption of photons from a light source and its subsequent loss to an adsorbed molecule. Unlike other methods, this technique does not result the formation of secondary contaminants (Yan et al., 2013; Danwittayakul et al., 2013; Bhattacharjee et al., 2014).

Utilization of renewable solar energy and development of efficient visible light-driven photocatalyst has become one of the most significant topics of research recently. A large number of reports are there on the photocatalytic degradation of organic contaminants/dyes under solar light irradiation by using various metal oxide photocatalysts such as:  $\text{Fe}_2\text{O}_3$  (Mahadik et al., 2013; Zhang et al., 2013; Bharadwaj et al., 2012),  $\text{BiFeO}_3$  (Soltani et al., 2013),  $\text{Cu}_2\text{O}$  (Ma et al., 2010),  $\text{TiO}_2$  (Kang et al., 2013; Chowdhury et al., 2012),  $\text{ZnO}$  (Sobana and Entezari, 2013),  $\text{CuO}$  (Mukherjee et al., 2011) and so on. However, the photocatalytic efficiency is suppressed by the rapid recombination rate and long migration distance of the photo-generated charge carriers. Therefore, designing and exploring photocatalysts with higher efficiency has attracted recent research efforts in the field of photo-catalysis (Hana et al., 2014). Use of heterogeneous/composite semiconductors can reduce the recombination rate of photo-generated electrons and holes and can be widely employed for improved photocatalytic efficiency. The formation of p-n heterojunctions in heteronanostructures can separate the photogenerated electron-hole pairs. This is mainly

because of the inherent establishment of the internal electric field directed from the n-type to p-type semiconductor (Han et al., 2013; Liu et al., 2015; Kumar et al., 2014).

We emphasize on the development of novel low cost solar light sensitive photocatalyst with excellent photo-degradation ability and universality for decomposing various organic pollutants. Among all other metal oxides, iron oxides are considered technologically important catalytic materials, sorbents, pigments, flocculants, coatings, gas sensors and ion exchangers. Iron oxide-based catalysts have been found to be good candidates as cheap and efficient catalysts, especially in environmental catalysis (Cao et al., 2008). Similarly, copper oxide (CuO) is a low cost, low toxicity and highly available metal oxide with band gap energy near visible light (Batista et al., 2010).

A valuable approach to further engineer  $\text{Fe}_2\text{O}_3$  properties consists in its surface modification or hybrid metal oxide composite formation by coupling with other metal oxide. Among the various possible options, an attractive choice is CuO, a biocompatible and inexpensive semiconductor oxide capable with a advantageous photocatalytic reactivity. The present work is an attempt to prepare rod shaped  $\text{Fe}_2\text{O}_3$ -CuO nanocomposite by thermal decomposition of oxalate precursor; which is an economical and facile solution state route. The prepared nanocomposites were used as novel photocatalyst under solar light that can decompose methyl orange, a carcinogenic dye, from aqueous solution. Methyl orange (an anionic azo dye) is one of the most important synthetic dye that has been widely used in textiles, foodstuffs, paper, and leather industries. The release of MO and its products in the environment cause harmful effects on human beings: it may cause eye or skin irritation, or inhalation may cause gastrointestinal irritation with nausea, vomiting, and diarrhea (Parida et al., 2008). From various recent literatures, we have found that  $\text{Fe}_2\text{O}_3$  and CuO nanomaterials are used as effective photocatalysts for degradation of methyl orange from aqueous system (Li et al., 2012; Sathyamoorthy and Mageshwari, 2013; Cao and Zhu, 2008; Zhou et al., 2009; Xie et al., 2009; Sharma et al., 2014). Hence, for further evaluation of the photocatalytic activity of prepared  $\text{Fe}_2\text{O}_3$ -CuO nanocomposite under solar light irradiation we have chosen methyl orange as the model organic dye in this work.

## **6.2. Materials and methods**

### **6.2.1. Materials**

Ferrous sulphate heptahydrate ( $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ ), copper chloride dihydrate ( $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ ), oxalic acid dihydrate ( $\text{H}_2\text{C}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ ), cetyltrimethyl ammonium bromide (CTAB), ethanol,

and Methyl orange were procured from Merck India. All the chemicals were used as received without any further purification.

### 6.2.2. Synthesis of $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite

$\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite were synthesized by a simple co-precipitation method using FeSO<sub>4</sub>·7H<sub>2</sub>O and CuCl<sub>2</sub>·2H<sub>2</sub>O as salt precursor, CTAB as structure directing agent and ethanol and double distilled water as solvent. For the preparation of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite, 0.7 g (2.5 mmol) of FeSO<sub>4</sub>·7H<sub>2</sub>O and 0.43 g (2.5 mmol) of CuCl<sub>2</sub>·2H<sub>2</sub>O were dissolved in distilled water with vigorous stirring to form solution-I and 0.63 g of oxalic acid and 0.5 g of CTAB were dissolved in ethanol with vigorous stirring to form solution-II. Then, solution-I was added drop wise to solution-II with continuous stirring to form yellowish green precipitate. After addition the stirring was continued for another 5 hours. Then, the precipitate obtained was centrifuged, washed thoroughly by ethanol and double distilled water and dried at 80 °C for 2 hours to form ferrous oxalate-copper oxalate nanorods. The obtained composite nanorod was calcined at 500 °C with heating rate 10 °C/min for 2 hours to form  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO composite nanorods. For comparison,  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and CuO samples were also prepared using the same method by using FeSO<sub>4</sub>·7H<sub>2</sub>O and CuCl<sub>2</sub>·2H<sub>2</sub>O as salt precursors and keeping reaction the other conditions same as that of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite synthesis.

### 6.2.3. Characterization techniques

The surface morphology of the prepared composite materials was characterized by a Nova Nano SEM 450 Field Emission scanning electron microscopy (FE-SEM) operated at an acceleration voltage of 15 and 20 kV. The size of the particle and selected area electron diffraction (SAED) pattern of the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite was observed using a high resolution transmission electron microscope (JEM-2100 HRTEM, Make-JEOL, Japan) with an acceleration voltage of 200 kV. The phases were identified by means of X-ray diffraction (XRD) by a Rigaku Ultima-IV X-ray diffractometer using Cu K $\alpha$  radiation ( $\lambda$  = 1.54156 Å) at a scan rate of 5°/min. FTIR spectra were recorded using Perkin-Elmer FTIR (Spectrum RX-I) spectrophotometer. X-ray photoelectron spectroscopy (XPS) was determined using a VG Scientific ESCA LAB Mk-II Spectrometer with Al K $\alpha$  radiation (1486.6 eV) at a takeoff angle at 45°. The UV-Visible absorbance spectra of the sample were recorded using Shimadzu spectrometer (model 2450) with BaSO<sub>4</sub> coated integration sphere in the range of 200-800 nm.

#### 6.2.4. Photocatalytic degradation study

The photodegradation efficiency of all synthesized catalysts was tested towards degradation of Methyl orange (MO) under natural solar light radiation. Initially a stock solution of 1 g/L was prepared by dissolving 1 g of MO in 1000 ml of double distilled water. In a typical experiment, 0.1 gm of catalyst was added to 100 ml of 20 mg/L MO solution in a 250 ml of beaker. Before irradiation, the suspension was magnetically stirred in dark for 2 hour to ensure the establishment of the adsorption/desorption equilibrium of the dye onto the surface of photocatalysts. Afterwards the solution was exposed to natural sunlight with continuous stirring. All the experiments were performed at the location of 22°15'N 84°54'E during the months of December and January (sunny days), from 11:00 AM to 12:30 PM, when the average solar intensity was 0.25 kW m<sup>-2</sup> with minimum fluctuation. During photoreaction 3 ml of the suspension was collected at 15 min time interval and centrifuged to remove the particles. After that, the MO concentration of the solution was analyzed by UV–VIS spectrometer (Shimadzu spectrometer, model-2450) at its maximum adsorption wavelength ( $\lambda_{\text{max}}$ ) of 463 nm. This process was repeated till the complete degradation of dye from the aqueous solution. The percentage of degradation of MO was calculated by the following equation (Dong et al., 2014):

$$\text{Percentage of degradation} = 100 \times \left( \frac{C_0 - C_t}{C_0} \right) \% \quad (6.1)$$

where  $C_0$  and  $C_t$  were the concentration of MO when reaction time was 0 and  $t$  and  $A_0$  and  $A_t$  were the absorbance of MO when reaction time was 0 and  $t$ , respectively.

### 6.3. Results and discussion

#### 6.3.1. Characterization of photocatalysts

The surface morphology and size of the nanocomposite photocatalysts were analyzed by FESEM and TEM. Figure 6.1 shows the SEM and high magnification FESEM (inset) images of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, CuO, and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite and TEM and SAED patterns of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite. Figure 6.1a represents the SEM and FESEM images of the as-synthesized  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods. The nanorods have smooth surfaces with the diameter in the range of 100-200 nm and the length up to micrometers. The SEM and FESEM images of CuO nanoparticles are shown in figure 6.1b; which indicate very fine spherical shaped particles with particle diameter in the range of 30-40 nm. Figures 6.1c, d represent SEM, FESEM and TEM images of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposites. From the figures it is observed that, there are numerous spherical CuO nanoparticles decorated on the surface of the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>

nanorods. These nanoparticles are uniformly distributed. The spherical nanoparticles of CuO are attached to the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods and oriented along one-dimensional direction to form  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO composite nanorods. The SAED pattern taken from (given in figure 6.11d) shows bright diffraction spots, due to high crystalline nature of the nanocomposite.

Figure 6.2 shows the SEM-EDS spectra of the prepared photocatalysts. The spectrum of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> indicates the presence of Fe and O elements, spectrum of CuO indicates the presence of Cu and O elements, while the spectrum of composite  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO indicates the presence of Fe, Cu and O elements. No other elements present in the spectrum besides Pt (which is used for coating). This indicates the prepared nanomaterials are highly pure.

**Figure 6.1** SEM and FESEM images of a)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorod, b) CuO nanoparticles and c)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite, d) TEM image and SAED patterns of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite.

**Figure 6.2** EDAXs of (a)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods, (b) CuO nanoparticles and (c)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite.

Figure 6.3 represents the XRD patterns of as prepared  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ ,  $\text{CuC}_2\text{O}_4 \cdot x\text{H}_2\text{O}$ , and  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ - $\text{CuC}_2\text{O}_4 \cdot x\text{H}_2\text{O}$  along with calcined  $\alpha\text{-Fe}_2\text{O}_3$ , CuO, and  $\alpha\text{-Fe}_2\text{O}_3$ -CuO nanocomposite. The XRD pattern in figure 6.3a contains the characteristics peaks of ferrous oxalate dihydrate ( $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ ) and can be index to orthorhombic crystal structure according to JCPDS No: 22-0635. Figure 6.3b contains the characteristics peaks of copper oxalate hydrate ( $\text{CuC}_2\text{O}_4 \cdot x\text{H}_2\text{O}$ ) and can be index to orthorhombic crystal structure according to JCPDS No: 21-0297. Similarly, the composite sample (figure 6.3c) contains characteristics peaks of both  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$  and  $\text{CuC}_2\text{O}_4 \cdot x\text{H}_2\text{O}$ . The XRD patterns of 500 °C calcined samples are shown in figure 6.3d-f. All diffraction peaks in figure 6.3d, and 6.3e are in good agreement with those of the standard patterns of rhombohedral  $\alpha\text{-Fe}_2\text{O}_3$  (JCPDS No: 79-0007) and monoclinic CuO (JCPDS Card No. 05-0661), respectively. Figure 6.3f represents two sets of diffraction peaks for the  $\alpha\text{-Fe}_2\text{O}_3$ -CuO sample, which are correspondingly ascribed to rhombohedral  $\alpha\text{-Fe}_2\text{O}_3$  and monoclinic CuO. All the X-ray diffractograms well defined, revealing the well-crystalline character of the samples. The broadening of the peaks also indicates the decrease in the diameter and an increase in the surface area to volume ratio of the compounds.

**Figure 6.3** X-ray diffraction patterns of (a)  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ , (b)  $\text{CuC}_2\text{O}_4 \cdot x\text{H}_2\text{O}$ , (c)  $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ - $\text{CuC}_2\text{O}_4 \cdot x\text{H}_2\text{O}$ , (d)  $\alpha\text{-Fe}_2\text{O}_3$  nanorods, (e) CuO nanoparticles and (f)  $\alpha\text{-Fe}_2\text{O}_3$ -CuO nanocomposite.

To investigate the chemical binding states of the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite, the XPS analysis was performed. Figure 6.4a shows the general survey spectrum of the nanocomposite, which reveals that the surface of the sample contains Fe, Cu, O and C elements. The chemical states of Fe and Cu were determined from Fe2p and Cu2p peaks, respectively. The high-resolution XPS spectra (figure 6.4b–d) of the mixed metal oxide show the presence of Cu 2p, Fe 2p and O 1s peaks. In figure 6.4b the peaks at about 956.05 and 934.27 eV are attributed to Cu 2p<sub>1/2</sub> and Cu2p<sub>3/2</sub>, respectively. Along with the two peaks of, the existence of strong shake-up features for Cu (2p) are the major XPS characteristics of CuO. Figure 6.4c displays the electron binding energies of 714.9 and 728.1 eV, which are due to the presence of Fe 2p<sub>3/2</sub> and Fe2p<sub>1/2</sub>, respectively and a satellite at 720.6 eV. These parameters correspond to the Fe<sup>3+</sup> surface species in  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> (Cao et al., 2008; Liu et al., 2009). The O 1s region (Figure 6.4d) can be deconvoluted into two peaks at about 533.6 and 535.5 eV, which indicates the existence of two different oxygen species. The XPS studies confirmed the existence of independent species of Fe<sub>2</sub>O<sub>3</sub> and CuO in the composite.

**Figure 6.4** (a) XPS pattern of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposites and high resolution XPS of (b) Cu2p, (c) Fe2p and O 1s core levels of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite.

The UV-vis absorption behavior of the prepared nanomaterials was analyzed due to their potential application in photo-irradiation. The optical absorption property and migration of the light-induced electrons and holes of a semiconductor are the key factors in determining its photo-catalytic activity (Hou et al., 2012). Figure 6.5a shows the UV-visible absorption spectra for  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, CuO and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposites. For  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, absorption bands at 548 and 377 nm corresponding to the ligand-free ( ${}^6A_1 \rightarrow {}^4E_g$ ) and a ligand-to-metal charge transfer ( $6t_{1u} \rightarrow 2t_{2g}$ ) transitions, respectively (Sivula et al., 2010). The steep shape of the absorption between 750 and 950 nm in case of CuO indicates that the light absorption is due to the intrinsic band-gap transition (Mageshwari et al., 2012). At lower wavelength, adsorption peaks are distinguished between 250 nm to 300 nm due to O<sup>2-</sup> to Cu<sup>2+</sup> charge-transfer transitions (Prasetyanto et al., 2007). In case of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposites, in addition to the peaks of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, steep shape of the absorption between 850 and 950 nm is observed. Figures 6.5b-d show the plot of the  $h\nu$  vs  $(F(R)h\nu)^2$  for different composite oxides. The direct band gap energy ( $E_g$ ) is calculated from the abscise interception. The band gap values of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, CuO and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO are 2.12, 1.47 and 1.85 eV respectively.

**Figure 6.5** (a) Optical absorbance spectra and calculated band-gap energy of (a)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods, (b) CuO nanoparticles and (c)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite.

#### 6.4. Photocatalytic degradation of MO in natural sunlight

The catalytic activity of the prepared photocatalysts was evaluated by heterogeneous degradation of methyl orange (MO) wastewater under natural solar light irradiation. All the experiments were conducted under following conditions: MO concentration 20 mg/L and catalyst concentration 1 g/L. The UV-Vis spectra of MO aqueous solution in the process of photodegradation are displayed figure 6.6a-c. From the figure it is observed that, the absorbance at 463 nm of MO diminishes gradually with time elapsed: which indicates the reduction of MO from orange to colorless. The absorption peak completely disappeared in 90 min in the presence of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite as photocatalyst. The photograph of MO solution before and after solar light irradiation is given in figure 6.6d, which also confirms the complete degradation of the MO in 90 min.

**Figure 6.6** UV-visible absorption spectra showing the temporal evolution of the degradation of MO upon sun-light irradiation using (a)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods, (b) CuO nanoparticles and (c)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite and (d) Optical image of the degradation of MO with the increase of time using  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite photocatalyst.

Figure 6.7 shows the percentage of degradation of MO with time. For the photocatalytic experiments, prior to solar light irradiation, the adsorption properties of the photocatalysts were initially studied. Prior to solar light irradiation, the reaction mixture was magnetically stirred for 120 min in dark in order to obtain a homogeneous suspension having adsorption–desorption equilibrium and the adsorption amount of all these photocatalysts for the MO was found to be negligible. After 90 min of solar light irradiation the degradation percentage of MO in the absence photocatalyst is only 3 % whereas it is observed to be 50.2, 86.5 and 99.9 % using  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, CuO and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO photocatalysts, respectively. From this result it is confirmed that the degradation of MO takes place due to the presence of these photocatalysts under solar light irradiation and the photocatalytic activity is found to follow a sequence:  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> < CuO <  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO. It is observed that  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite demonstrated the highest photocatalytic activity, and the MO can be completely degraded under solar light irradiation within 90 min reaction.

**Figure 6.7** Percentage of degradation of MO as a function of reaction time by using  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods, CuO nanoparticles and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite.

The kinetics of degradation can be mainly studied by pseudo-first-order equation. According to Langmuir–Hinshelwood model, when the initial concentration  $C_0$  is very small the following pseudo-first-order rate equation is used (Tanveer et al., 2014):

$$\ln(C_0/C_t) = K_1 t \quad (6.2)$$

where  $K_1$  is pseudo first order rate constant ( $\text{min}^{-1}$ ) and  $C_t$  is the concentration at time  $t$ . A plot of  $\ln(C_0/C_t)$  vs  $t$  gives the value of  $K_1$ . The reaction rate constants ( $K_1$ ) for all the three

photocatalysts were determined from the slope of the fitted curves (figure 6.8) by means of linear regression and the values are given in table 6.1. A good linear relationship between  $\ln(C_0/C_t)$  and the irradiation time is observed for all the photocatalyst and the rate constant for  $\alpha\text{-Fe}_2\text{O}_3\text{-CuO}$  photocatalyst is highest i.e.  $0.0827 \text{ min}^{-1}$  with good regression constant value ( $R^2=0.9534$ ), showing  $\alpha\text{-Fe}_2\text{O}_3\text{-CuO}$  nanocomposite is the best among them.

**Table 6.1** Percentage of degradation and pseudo-first-order kinetic parameters of MO.

Photocatalyst	Degradation (%)	$K_1 (\text{min}^{-1})$	$R^2$
$\alpha\text{-Fe}_2\text{O}_3$	50.2	0.0072	0.9015
CuO	86.5	0.0224	0.9373
$\alpha\text{-Fe}_2\text{O}_3\text{-CuO}$	99.9	0.0827	0.9534

**Figure 6.8** Pseudo-first-order reaction kinetic linear relationship curves for degradation of MO by (a)  $\alpha\text{-Fe}_2\text{O}_3$  nanorods, (b) CuO nanoparticles and (c)  $\alpha\text{-Fe}_2\text{O}_3\text{-CuO}$  nanocomposite.

The stability of catalysts is an important issue for their practical applications. To prove the stability and the reusability of  $\alpha\text{-Fe}_2\text{O}_3\text{-CuO}$  nanocomposite photocatalyst, we have repeated the experiments consecutive four cycles for degradation of the MO and the result is shown in figure 6.9. It is observed that, the repeatability of the entire process and the final results of degradation of MO are very good, which further demonstrate the excellent efficiency of the photocatalyst.

**Figure 6.9** Repeating experiments for the photocatalytic degradation of MO using  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite under solar light irradiation.

**Photocatalytic Mechanism:** The photocatalytic processes are based on electron hole pairs generated from band gap excitation. The photoinduced electron-hole pairs migrate to the surface of the materials and react with the adsorbed reactants in the due process, or undergo an undesired recombination. Therefore, the generation and separation of the photoinduced electron-hole pairs are the key factors that influence a photocatalytic reaction. From the experimental result, it is observed that CuO deposition have improved the photocatalytic activity of the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorod. Although  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> has a narrow bandgap and good absorption in the visible region, the still narrower bandgap of CuO modified the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods such that they were activated by solar light absorption. The  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorod is an n-type semiconductor with bandgap 2.12 eV and CuO is a p-type semiconductor with bandgap 1.47 eV. The  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite system formed a stable p-n junction that efficiently separated electron-hole pairs that were photogenerated within each semiconductor material. Efficient charge separation contributed to the enhanced photocatalytic activity of the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO heteronanostructures (Ren et al., 2013; Jung et al., 2011; Chen et al., 2012). In CuO there is a chance of recombination of photo-formed electrons and holes due to small band gap. But in  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite, when the CuO is excited by solar light with photon energy higher than band gaps of CuO, the electrons in the valence band (VB) move to the conduction band (CB) generating equal amounts of holes in VB. The photogenerated electrons are migrated from the CB of CuO to the CB of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> forming different valence bond edges. Which inhibits electron-hole recombination: as a result the electron-hole pairs

react with the adsorbed molecules (dye molecules). The proposed mechanism of photocatalytic decomposition of MO can be described as follow (Shi et al., 2014):

**Figure 6.10** Proposed mechanism of photocatalytic degradation of MO using  $\alpha\text{-Fe}_2\text{O}_3\text{-CuO}$  nanocomposite.

Here, the generated conduction band electrons ( $\text{e}^{-}$ ) react with dissolved oxygen molecules to yield superoxide radical anions ( $\bullet\text{O}_2^{-}$ ). The superoxide radical ion reacts with water to form hydrogen peroxide which on further decomposition produces hydroxyl radical ( $\bullet\text{OH}$ ). Again, the generated valence band holes ( $\text{h}^{+}$ ) reacts with water to generate hydroxyl radical ( $\bullet\text{OH}$ ). The hydroxyl radical ( $\bullet\text{OH}$ ) is a strong oxidizing agent causes the degradation of dye

molecules. Schematic of photocatalytic mechanism in aqueous solution for the degradation of methyl orange by  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite is illustrated in figure 6.10.

## 6.5. Conclusion

In summary, we have synthesized solar light sensitive photocatalysts of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods, CuO nanoparticles and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposites with various morphologies by a facile low cost wet chemical method. XRD result gives the well crystalline nature of the prepared samples with appropriate phase without the presence of any impurity. FE-SEM images indicate formation of rod shaped  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanomaterials with diameter 100-200 nm and spherical shaped CuO nanoparticles with particle diameter 30-40 nm. But in case of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposite, the very fine spherical CuO particles are attached to the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorod and oriented in one-dimensional manner. XPS studies also confirmed the formation of Fe<sub>2</sub>O<sub>3</sub>-CuO composite nanomaterials. The narrow band gap semiconducting nature of the samples was analyzed by UV-Vis-DRS technique. The band-gap  $E_g$  of values of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, CuO and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO, calculated by the Kubelka–Munk function, are found to be 2.12, 1.47 and 1.85 eV, respectively. This prepared nanomaterial catalysts were used for photocatalytic degradation of Methyl orange under natural solar light. It was observed that the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO nanocomposites show enhanced photocatalytic activity compared to both individual  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and CuO nanoparticles. The enhanced photocatalytic activity is due to the efficient separation of photogenerated electron–hole pairs in the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>-CuO heteronanostructures.

## CHAPTER-7

# HYDROTHERMAL SYNTHESIS AND ENHANCED PHOTOCATALYTIC ACTIVITY OF TERNARY $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$ NANOCOMPOSITE THROUGH CASCADE ELECTRON TRANSFER

### 7.1. Introduction

Semiconducting metal oxide nanoparticles have received remarkable attention because of their potential application for the removal of organic pollutants from aqueous media through photocatalytic degradation (Khakpash et al., 2012; Qurashi et al., 2010; Zhang et al., 2015; Xing et al., 2015). The semiconductor photocatalysis process utilizes energy from solar light especially visible light or UV light to clean water, air and Surfaces. The basic decomposition process can be described as (Asiltürk et al., 2009; Alshammari et al., 2015; Vignesh et al., 2015):

Here minerals are generated from hetero atoms such as S, N and Cl, containing organic pollutants and  $E_g$  is the band gap of the semiconductor. During the photocatalytic process, electron-hole pairs are generated in valence and conduction bands of a semiconductor due to presence of free radical, attack the molecules of pollutants (Gómez-Solís et al., 2012).

Generally, semiconducting metal oxide such as:  $\text{TiO}_2$ ,  $\text{WO}_3$ ,  $\text{MnO}_2$ ,  $\text{CeO}_2$  and  $\text{ZnO}$ , are used in photocatalytic degradation process (Liu et al., 2011; Kole et al., 2013). All these metal oxides are wide band semiconductors; hence these materials can only be used be excited for photocatalysis under UV light irradiation. It is known that more than 90% solar light reaches earth surface is in the range of visible light (mostly 400–600 nm) since most UV is filtered by ozone layer. Thus, it is a challenging area of research to develop novel photocatalysts with high efficiency of utilization of solar irradiation, high energy transfer efficiency, nontoxicity and low cost. Photocatalysis with artificial light sources need high electrical power which is costly and hazardous, but solar energy is an abundant natural source of energy, which will meet the requirements of future environmental and energy technologies (Wu and Chen, 2004; Li and Wang, 2010; Kim et al., 2005; Muruganandham and Swaminathan, 2004). Among the candidate materials, different forms of iron oxides, because of their small band gaps are

considered to very suitable materials for solar light driven photocatalytic reaction. The band gap of  $\alpha\text{-Fe}_2\text{O}_3$  is around 2.2 eV, which can be activated with visible light region and collects up 40 % of the solar spectrum energy (Jang et al., 2009; Karunakaran and Senthilvelan, 2006). The drawbacks of  $\alpha\text{-Fe}_2\text{O}_3$  materials are high electron-hole recombination rates, small optical absorption coefficient in the visible region, and short hole diffusion lengths. To overcome these disadvantages, one of the important factors is using nanostructuring techniques i.e. using  $\alpha\text{-Fe}_2\text{O}_3$  nanomaterial to increase performance of  $\alpha\text{-Fe}_2\text{O}_3$  for photoresponse. Because nanomaterials exhibit large surface area compared to bulk counterpart, without an increase of the geometric area, reduced the scattering of free electrons, and enhanced the electrons mobility (Zhang et al., 2010). Similarly, another promising approach to overcome this disadvantage is making composite with  $\alpha\text{-Fe}_2\text{O}_3$  by coupling with other wide band gap semiconductors such as: ZnO,  $\text{TiO}_2$ ,  $\text{SnO}_2$ , etc. As a result the performance the composite increases by mutual transfer of charge carriers i.e. electron excited under visible light may transfer from the conduction band of narrow band gap semiconductor to that of wide band gap semiconductor inside the composite. Thus positive charged electron centers could be formed with compatible chemical and electrical properties, which may lead to great improvement of photocatalytic efficiency of the composite (Zhang et al., 2007). Recently, a number of research groups studied the photocatalytic activity of nanocomposite such as:  $\text{Fe}_2\text{O}_3\text{-ZnO}$  (Liu et al., 20007),  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Xia et al., 2008),  $\text{ZnO-CuO}$  (Li and Wang, 2010),  $\text{TiO}_2\text{-Fe}_2\text{O}_3$  (Zhou et al., 2008),  $\text{CeO}_2\text{-SiO}_2$  (Mohamed and Aazam, 2012),  $\text{Fe}_2\text{O}_3\text{-TiO}_2$  (Peng et al., 2010),  $\text{SnO}_2\text{-Fe}_2\text{O}_3$  (Kang et al., 2011), and so on. They found that these composite semiconductor photocatalysts show enhanced photocatalytic efficiency and also exhibit fine optical properties compared to the corresponding parent component. Many binary metal oxide nanocomposites have been studied for this purpose, and the overall activity can be even more enhanced if a ternary hybrid system is employed (Kim et al., 2011). Hence, very recent research focused on designing multiple heterojunction structures with improved photogenerated electron-hole separation by engineering the energy band (Sun et al., 2014). Researchers are preparing ternary metal oxide nanocomposites by multi-step synthesis; which is difficult for large scale production due to high cost, long time taken and complex process (Kim et al., 2011; Sun et al., 2014).

In the present work, we have selected Zn salt with iron salt precursor to form mixed oxide  $\text{Fe}_2\text{O}_3\text{-ZnO}$  composite nanomaterials by maintaining identical reaction conditions using hydrothermal method. Interestingly we have observed the formation of  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$

ternary nanocomposite in single step by changing molar ratios of Fe and Zn. The synthesized novel  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  nanocomposite oxides were used as photocatalysts towards catalytic degradation of organic contaminants/dye (Malachite green) from aqueous media. The hydrothermal method was chosen as the preferred method for the synthesis of ternary composite in order to achieve high surface area and morphology control which are essential parameters which affects the photocatalytic performance. For photocatalytic degradation purpose we use cationic dye like Malachite green. Malachite green (MG), a triarylmethane dye, has been extensively used in the textile industry for dyeing wool and silk, and also has a widespread use in the paper, leather, and pharmaceutical industries. It is also used illegally for various purposes including in aquaculture as a fungicide on larvae and juvenile fish, as a parasiticide, and in the food, textile and other industries. Hence, relatively high levels of MG are always present in industrial wastewaters, and are harmful to human and others due to its genotoxic and carcinogenic properties, including its effects on the immune system and reproductive system and cause carcinogenesis, mutagenesis, teratogenicity, genotoxicity and respiratory toxicity. Thus, it is of particular significance to efficiently remove MG from wastewaters (Chen et al., 2007; Ju et al., 2008).

## **7.2. Materials and Methods**

### **7.2.1. Materials used**

Ferric nitrate ( $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ ) from s d Fine-Chem limited, Zinc sulphate ( $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$ ) from Universal laboratory, Ethylenediamine from Merck India, Oxalic acid dehydrate from Merck India, Malachite green (MG) from Merck India, and Ethanol from Merck Germany. All the reagents used in the synthesis and catalytic study were of analytical grade and used as received without further purification.

### **7.2.2. Synthesis of $\alpha\text{-Fe}_2\text{O}_3$ nanoparticles**

Iron oxide ( $\alpha\text{-Fe}_2\text{O}_3$ ) was synthesized by hydrothermal method keeping the starting material ferric nitrate ( $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ ). 1.212 gm of ferric nitrate was dissolved in 150 ml of water under vigorous stirring. Under this condition 10 g of ethylenediamine was added drop wise for maintain the pH 11. After the addition of ethylenediamine, a brown precipitate was formed and the stirring was continued for half an hour to form a homogeneous solution. Then the solution was kept into a Teflon-lined sealed autoclave followed by hydrothermal treatment at 150 °C for 12 hr. Then the sample was washed and centrifuged for several times with ethanol and distilled water and then dried at 60 °C for 2 hours. Then the dried sample

was calcined at 500 °C for 2 hours with heating rate 10 °C/min to form  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles.

### 7.2.3. Synthesis of $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>/ ZnFe<sub>2</sub>O<sub>4</sub>/ZnO nanocomposites

For the synthesis of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub> mixed nanocomposite, we followed the same above hydrothermal procedure, taking the starting materials ferric nitrate and zinc sulphate (ZnSO<sub>4</sub>·7H<sub>2</sub>O) by varying the molar ratio ferric nitrate: Zinc sulphate = 90:10, 80:20, 70:30, 60:40 and 50:50 followed by calcination at 500 °C to form Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>, Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO and ZnFe<sub>2</sub>O<sub>4</sub>/ZnO nanocomposites. The details of the synthesis of Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO nanocomposites are schematically presented in Scheme 7.1.

**Scheme 1** Schematic representation of the synthesis of Fe<sub>2</sub>O<sub>3</sub>/ ZnFe<sub>2</sub>O<sub>4</sub>/ZnO nanocomposite.

### 7.2.4. Characterization techniques

The surface morphology of the prepared composite materials was characterized by a Nova Nano SEM 450 Field Emission scanning electron microscopy (FE-SEM) operated at an acceleration voltage of 15 and 20 kV. The size of the particle and selected area electron diffraction (SAED) pattern of the nanocomposite was observed using a high resolution transmission electron microscope (JEM-2100 HRTEM, Make-JEOL, Japan) with an acceleration voltage of 200 kV. The phases were identified by means of X-ray diffraction (XRD) by a PANalytical X-ray diffractometer with Cu K $\alpha$  radiation ( $\lambda$ ) 1.54156 Å at a scan rate of 2°/min. X-ray photoelectron spectroscopy (XPS) was determined using a VG Scientific ESCA LAB Mk-II Spectrometer with Al K $\alpha$  radiation (1486.6 eV) at a takeoff angle at 45°. The UV-Visible absorbance spectra of the sample were recorded using Shimadzu spectrometer (model 2450) with BaSO<sub>4</sub> coated integration sphere in the range of 200-800 nm. Specific surface area and pore size distribution (PSD) of the samples were determined from nitrogen adsorption/desorption isotherms obtained at the temperature of liquid nitrogen in an automated physisorption instrument (Autosorb-iQ,

Quantachrome Instruments). Steady-state fluorescence emission spectra were recorded using Jobin-Yvon Spectrofluorimeter (Fluoromax-4P) at an excitation wavelength of 420 nm with 5/5 slit.

#### **7.2.5. Photocatalytic activity study**

The photodegradation efficiency of all synthesized catalysts was tested towards degradation of Malachite green (MG) under natural solar light radiation. All the experiments were performed at the location of 22°15'N 84°54'E during the months of May and June (sunny days), from 09.00 AM to 11:00 A. M., when the average solar intensity was  $1.0 \text{ kW m}^{-2}$  with minimum fluctuation. Initially a stock solution of 1 g/L was prepared by dissolving 1 g of Malachite green (oxalate) in 1000 ml of double distilled water. In a typical experiment, 0.1 gm of catalyst was added to 100 ml of 20 mg/L MG solution in a 250 ml of beaker. Before irradiation, the suspension was magnetically stirred in dark for 2 hour to ensure the establishment of the adsorption/desorption equilibrium of the dye onto the surface of photocatalysts. Afterwards the solution was exposed to natural sunlight with continuous stirring. At given time interval (every 15 min) the solution (3 ml) sampled and filtered. Then the solution was put into a quartz cell, and adsorption spectrum was measured using Shimadzu UV-2450 spectrometer. This process was repeated until complete degradation of dye from the aqueous solution. TOC before and after 90 min of photodegradation studies was measured using a TOC analyzer (SHIMADZU TOC-L).

### **7.3. Results and Discussion**

#### **7.3.1. Detailed characterizations and properties of the prepared nanocomposites**

**Morphology and compositional analysis:** FE-SEM images and EDAX pattern of the synthesized  $\alpha\text{-Fe}_2\text{O}_3$  nanoparticles and the nanocomposites with different molar proportion of Fe and Zn are shown in figure 7.1. Figure 7.1a shows the FESEM image of  $\alpha\text{-Fe}_2\text{O}_3$  nanoparticles. The image suggests the formation of very fine particles with irregular shape and morphology. The sizes of the particles are in the range of 80-100 nm. Figures 7.1b-f represents the FESEM images of  $\alpha\text{-Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  nanocomposites prepared by varying mole % of iron and zinc. From the images it is observed that, with increasing percentage of Zn in the nanocomposite the morphology of the nanocomposites gradually changes from irregular (for  $\alpha\text{-Fe}_2\text{O}_3$ ) to cubical and when Zn percentage reaches 50 % the shape of the nanocomposite becomes cubical with uniform size. The sizes of all the nanocomposites are in the range of 100-200 nm. The EDAX patterns of  $\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe: Zn=50:50) is shown in

figure 7.1g. The patterns demonstrate that the nanocomposite contains O, Fe and Zn elements. The transmission electron micrographs and SAED pattern of  $\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=50:50) nanocomposite are shown in figure 7.2. From figure 7.2a-c, it is observed that, apart from some irregular particles the major morphological feature is regular cubic shape with mean edge length in the range 100-200 nm. Figure 7.2d shows the corresponding SAED pattern of the nanocomposite, which demonstrates the crystalline nature.

**Figure 7.1** FE-SEM images of a)  $\alpha\text{-Fe}_2\text{O}_3$ , b)  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4$  (Fe:Zn=90:10), c)  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4$  (Fe:Zn=80:20), d)  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30), e)  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=60:40), f)  $\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=50:50) and EDAX pattern of  $\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=50:50).

**Figure 7.2** (a-c) TEM images and (d) SAED pattern of  $\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=50:50).

**XRD analysis:** Figure 7.3 shows the XRD patterns of the  $\alpha\text{-Fe}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4$  and  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  nanocomposites (with different molar ratios). The pattern of  $\alpha\text{-Fe}_2\text{O}_3$  (figure 7.3a) contains characteristics peaks at  $2\theta = 24.12^\circ, 33.15^\circ, 35.62^\circ, 39.21^\circ, 40.85^\circ, 49.47^\circ, 54.08^\circ, 57.62^\circ$  and  $62.44^\circ$  (marked as:  $\alpha$ ) and can be indexed as (012), (104), (110), (112), (024), (116), (018), (214) and (300) reflections, respectively of the rhombohedral crystal structure of  $\alpha\text{-Fe}_2\text{O}_3$  according to JCPDS No: 79-0007. Figure 7.3b-f show the XRD patterns of nanocomposite system prepared by taking  $(100-x)$  mole %  $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$  and  $x$  mole %  $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$  as the initial precursors (where  $x=10, 20, 30, 40$  and  $50$ ). For  $x = 10$  (figure 7.3b), the presence of  $\text{ZnFe}_2\text{O}_4$  with cubic crystal structure peaks are detected according to JCPDS card no. 22-1012; which confirms its formation along with  $\alpha\text{-Fe}_2\text{O}_3$ . The prominence of peaks (figure 7.3c) corresponding to  $\text{ZnFe}_2\text{O}_4$  for  $x = 20$  in expense of parent phase indicates the evolution of a well composite system of  $\alpha\text{-Fe}_2\text{O}_3$  and  $\text{ZnFe}_2\text{O}_4$ . When  $x$  varied to 30, the appearance of some new peaks is observed which are detected to be of ZnO compound with hexagonal wurtzite crystal structure according to JCPDS no: 01-1136, but simultaneously parent phase also found to be weakened. The presence of ZnO phase

gradually increases with  $\text{ZnFe}_2\text{O}_4$  as their corresponding peaks become more prominent for next higher percentage of  $x = 40$ , shown in figure 7.3d, along with minute presence of  $\alpha\text{-Fe}_2\text{O}_3$  phase. This confirms a well formulated composite system with the presence of three compounds. For  $x = 50$ , the peaks corresponding to  $\alpha\text{-Fe}_2\text{O}_3$  is completely absence in the XRD pattern (figure 7.3e). But the corresponding peaks of other two compounds still appear which indicates the formation of a composite system of  $\text{ZnFe}_2\text{O}_4$  and  $\text{ZnO}$ .

**Figure 7.3** XRD patterns of a)  $\alpha\text{-Fe}_2\text{O}_3$  nanoparticle, b)  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4$  (Fe:Zn=90:10), c)  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4$  (Fe:Zn=80:20), d)  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30), e)  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=60:40), f)  $\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=50:50) nanocomposites.

**XPS analysis:** Figure 7.4a gives the full XPS survey spectrum for the  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30) nanocomposite. The presence Fe, Zn, O and C elements are observed from the spectra. Carbon is due to the adventitious hydrocarbon from the XPS instrument itself. Figure 7.4b displays the high resolution XPS spectra of Fe 2p, in which two peaks at 712.7 and 726.8 eV correspond to Fe 2p<sub>1/2</sub> and Fe 2p<sub>3/2</sub>, respectively. In addition, the presence of satellite peak at 718.3 suggests that only  $\text{Fe}^{3+}$  exists in the nanocomposite. The high resolution spectrum of Zn 2p is displayed in figure 7.4c. The peaks at binding energy of 1043.5 and 1022.1 eV can be attributed to Zn 2p<sub>1/2</sub> and Zn 2p<sub>3/2</sub>, respectively. It suggests that the oxidation state of Zn is 2+ in the present nanocomposites. The spectrum of O 1s is

shown in figure 7.4d. The broad asymmetric curve can be de-convoluted into three peaks with binding energies at 532.8, 531.6 and 530.2 eV, respectively. The peak at 530.2 eV is due to surface lattice oxygen ( $O^{2-}$ ) in metal oxide framework and the other peaks at around 531.6 and 532.8 eV are ascribed to surface adsorbed oxygen species such as  $O^-$  and  $O_2^-$  (Lv et al., 2010; Wang et al., 2015).

**Figure 7.4** XPS patterns of (a) survey, (b) Fe 2p, (c) Zn 2p, (d) O 1s of the  $Fe_2O_3/ZnFe_2O_4/ZnO$  (Fe:Zn=70:30) nanocomposite.

**UV-Vis-DRS study and calculation of band gap:** Because of the importance of the optical absorption properties and the electronic nature of band gap of the prepared nanocomposites for solar energy photocatalytic reaction, we have studied changes in the optical properties of pure  $\alpha$ - $Fe_2O_3$  nanoparticle with addition of Zn to form  $\alpha$ - $Fe_2O_3/ZnFe_2O_4/ZnO$  nanocomposite, by UV-vis spectroscopy. The band-gap  $E_g$  can be calculated by the Kubelka-Munk function (Mariappan et al., 2015):

$$(\alpha h\nu)^2 = B (h\nu - E_g)^n \quad (7.2)$$

where  $h\nu$  is the photon energy,  $\alpha$  is the absorption coefficient,  $B$  is a constant. The band-gap can be derived from the plot of the Kubelka-Munk function versus the absorption energy. The value of  $n$  is determined from the nature of optical transition.  $n=2$  or 3 for indirect

allowed and indirect forbidden transition, respectively and  $n=1/2$  or  $3/2$  for direct allowed and direct forbidden transition, respectively. The band-gap of all the synthesized photocatalysts is shown in figure 7.5b-g. It is estimated from the plot of  $(\alpha h\nu)^n$  versus  $h\nu$  by extrapolating the straight line to the X axis intercept. From the graph it is observed that there is a sharp increase of the absorptivity between wavelength range 550 and 600 nm. Figure 7.5a shows the absorption coefficient,  $\alpha$ , as a function of wavelength for pure  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO nanocomposites. For  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, absorption bands at 593 and 366 nm corresponding to the ligand-free ( ${}^6A_1 \rightarrow {}^4E$ ) and a ligand-to-metal charge transfer ( $6t_{1u} \rightarrow 2t_{2g}$ ) transitions, respectively (Sivula et al., 2010). Upon increasing percentage of Zn in the composite from 0 % to 20 %, the adsorption edges show a red shift and also increases in intensity of the absorption spectra in the visible light region compared to  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>. The red shift indicated that the band gap of the composite decreases and the size quantization effect exists (Frost et al., 2006). The band-gap energy of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> is 2.42. When percentage of Zn in the composite increases to 20 %, the band-gap adsorption edge shifted to 631 nm, indicating that the  $E_g$  is 2.08 eV. However, further increasing the Zn amount to 30 % in the composite brings a slightly blue shift of the maximum adsorption peak and band-gap adsorption edge. The band gap of Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=70:30) is 2.01. The slightly blue shift and increase in band gap of the composite is due to formation of a small amount of ZnO in the nanocomposite. When the percentage of Zn again increases to 40 and 50 %, the band gap of the composites increases to 2.03 and 2.55 for Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=60:40) and ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=50:50) nanocomposites respectively. The increase in band gap for the nanocomposite is due to formation of extra ZnO phase in the nanocomposites.

**Surface area and porosity measurement:** Based on N<sub>2</sub> adsorption-desorption measurements, the isotherms and corresponding pore size distribution curves for prepared  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO nanoparticles are shown in figure 7.6. The BET surface area of pure  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticle was found to be very low i.e. 18.555 m<sup>2</sup>/g. But in case of composites the surface areas were found to be 21.2, 26.076, 32.775, 38.494 and 49.464 m<sup>2</sup>/g for Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub> (Fe:Zn=90:10), Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub> (Fe:Zn=80:10), Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=70:30), Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=60:40) and ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=50:50), respectively. It is observed that with increasing percentages of Zn in the nanocomposites the surface area increases slowly. From the BJH pore size distribution curve sharp peaks were observed at 2.5, 3.4, 3.4, 3.8, 3.3 and 3.5 nm for  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub> (Fe:Zn=90:10), Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub> (Fe:Zn=80:10), Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=70:30), Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO

(Fe:Zn=60:40) and  $\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=50:50), respectively; which demonstrates the existence of inter-particle voids with pore-size distribution in the nanostructures.

**Figure 7.5** a) Optical absorption spectra and b) calculated band-gap energy of b)  $\alpha\text{-Fe}_2\text{O}_3$  nanoparticle, c)  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4$  (Fe:Zn=90:10), d)  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4$  (Fe:Zn=80:20), e)  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30), f)  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=60:40), g)  $\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=50:50) nanocomposites.

**Figure 7.6** BET isotherm of and Pore size distribution curves (incet) based on the BJH method for a)  $\alpha$ - $\text{Fe}_2\text{O}_3$  nanoparticle, b)  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4$  (Fe:Zn=90:10), c)  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4$  (Fe:Zn=80:20), d)  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30), e)  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=60:40), f)  $\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=50:50) nanocomposites.

### 7.3.2. Photocatalytic degradation of MG under solar light irradiation

The photocatalytic activities of the prepared  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticle, Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>, Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO and ZnFe<sub>2</sub>O<sub>4</sub>/ZnO nanocomposites with variable Fe:Zn ratios are evaluated by photocatalytic degradation of MG from aqueous solution under natural sunlight irradiation by monitoring the intensity of the characteristic absorption peak at 618 nm of malachite green. The degradation percentage of MG was calculated by the following equation:

$$\text{Degradation percentage} = 100 \times \left( \frac{C_0 - C_t}{C_0} \right) \% = 100 \times \left( \frac{A_0 - A_t}{A_0} \right) \% \quad (7.3)$$

where  $C_0$  and  $C_t$  were the concentration of MG when the reaction time was 0 and  $t$  and  $A_0$  and  $A_t$  were the absorbance of MG when the reaction time was 0 and  $t$ , respectively. The UV-vis spectral changes of MG aqueous solution in the process of photodegradation for Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=70:30) nanocomposites is displayed figure 7.7. From the figure it is observed that, the absorbance at 618 nm of MG diminishes gradually with time elapsed: which indicates the reduction of MG from blue to colorless. The absorption peak completely disappeared in 90 min. The photograph of MG solution before and after solar light irradiation with different time is given in figure 7.7 (inset), which also confirms the complete degradation of the MG in 90 min.

**Figure 7.7** UV-vis spectral changes and optical images (inset) of Malachite green during degradation process as a function of reaction time using Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=70:30) nanocomposite Photocatalyst (100 ml of 20 mg L<sup>-1</sup> MG solution, 0.1 g catalyst and natural solution pH).

**Effect of pH of the solution:** The solution pH is a significant parameter in photocatalytic degradation process. The influence of different pH (4-8) value on the degradation efficiency of MG was investigated using 0.1 g of  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30) photocatalyst in 100 ml of 20 mg/L MG solution and the result is shown in figure 7.8. The natural pH value of 20 mg/L MG solution was found to be 5.7. The pH value was adjusted using dilute HCl or dilute NaOH solution for the experiment. Before the irradiation to sunlight, the MG solutions with the photocatalyst was kept in dark condition with constant stirring for 2 h, but the reduction in concentration was found to be around 2 %; this might be due to adsorption rather than photodecomposition. However with the exposure of sunlight, the performances of the photoreaction were extremely improved. The experimental results reveal that the percentage of degradation increases with pH. The increase in rate of photocatalytic degradation might be due to the more availability of  $\text{OH}^-$  ions in alkaline medium which will generate more  $\bullet\text{OH}$  radicals by combining with holes which are formed due to the electronic excitation in catalyst (Pare et al., 2011). For more alkaline solution pH ( $\text{pH} \geq 10$ ), it was observed a total decolorization of malachite green within a few seconds. This is because, malachite green dye changes to a colorless leuco compound at highly alkaline medium (Charanpahari et al., 2015). Hence, all further experiments were done at the natural pH of the dye solution.

**Figure 7.8** Variation of percentage degradation of 100 ml of 20 mg L<sup>-1</sup> MG with different pH using 0.1 g of  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30) nanocomposite under solar light irradiation.

**Effect of dye solution concentration:** The effect of initial dye concentration of MG was investigated using 0.1 g of  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30) photocatalyst in 100 ml of dye solutions of different concentrations ranging from 10 to 40 mg L<sup>-1</sup>. From figure 7.9, it is

observed that the percentage of degradation was found to be almost same for 10 and 20 mg L<sup>-1</sup> concentrations of dye. Before the irradiation to sunlight, the adsorption of MG solutions with the photocatalyst was studied in dark condition with constant stirring for 2 h, but the sorption percentage was found to be 0.5–2%. The percentage of degradation under solar light irradiation was found to decrease with increase in dye concentration. The reason for this decrease is attributed to the shielding effect of dye at high concentration that hinders the penetration of solar light to the dye molecules deposited over the catalyst surface (Tarigh et al., 2015). Hence, further experiments were carried out with 20 mg L<sup>-1</sup> concentration of dye.

**Figure 7.9** Variation of percentage degradation of 100 ml of MG with different concentration using 0.1 g of Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=70:30) nanocomposite under solar light irradiation.

**Effect of catalyst compositions and kinetics study:** Figure 7.10a shows the percentage of photodegradation and figure 7.10b shows the decrease in concentration of malachite green with respect to time using 0.1 g of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticle and Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub> (Fe:Zn=90:10), Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub> (Fe:Zn=80:10), Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=70:30), Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=60:40) and ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=50:50) nanocomposites catalysts each in 100 ml of 20 mg L<sup>-1</sup>. In the absence of catalyst, no degradation of MG dye was observed (not shown in graph) which indicated that photolysis did not occur under solar light. We have repeated the sorption experiment in dark, prior to photocatalysis studies in all the experiments as described previously. The decrease in dye concentration due to adsorption is found to be around 2% in all cases. It is observed that the proportion degradation of MG increases with increase in solar light exposure time and almost all the MG molecules were decomposed within 90 min with

$\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30) nanocomposite photocatalyst. When  $\alpha\text{-Fe}_2\text{O}_3$  nanoparticle was used as photocatalyst the percentage of degradation was 81.86 % after 90 min of irradiation. The degradation percentages are more in case of nanocomposites i.e. 88.37, 94.37 and 99.77 % after 90 min irradiation time using  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4$  (Fe:Zn=90:10),  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4$  (Fe:Zn=80:20) and  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30) nanocomposites, respectively. The percentage of degradation again decreased when percentage of Zn in the nanocomposites increased i.e. 98.29 and 96.92 % for  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=60:40) and  $\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=50:50) nanocomposites, respectively. Hence, it may be inferred that addition of Zn effectively enhances the photocatalytic activity of  $\alpha\text{-Fe}_2\text{O}_3$  up to 30 % and upon further addition up to 40 and 50 %, the photocatalytic activity decreases (figure 7.10c).

**Figure 7.10** a) percentage of photocatalytic degradation, b) concentration changes of MG, c) degradation of MG over all the synthesized photocatalysts and, d) pseudo-first-order reaction kinetic linear relationship curves for different photocatalysts (100 ml of 20 mg L<sup>-1</sup> MG solution, 0.1 g catalyst and natural solution pH).

The degradation patterns suggested that the degradation of MG followed a pseudo-first order kinetic model and the rate constant could be determined according to the following equation (Chandraboss et al., 2015):

$$\ln\left(\frac{C_0}{C_t}\right) = kKt = k_{app}t \quad (7.4)$$

where  $r$  is the reaction rate ( $\text{mol L}^{-1} \text{min}^{-1}$ ),  $C_0$  is the initial concentration of MG dye ( $\text{mol L}^{-1}$ ),  $C_t$  is the concentration of MG dye at time  $t$  ( $\text{mol L}^{-1}$ ),  $t$  is the irradiation time (min),  $k$  is the reaction rate constant ( $\text{min}^{-1}$ ),  $K$  is the adsorption coefficient of dye on a photocatalyst particle ( $\text{L mol}^{-1}$ ). Figure 7.10d shows the graph of  $\ln(C_0/C_t)$  versus reaction time ( $t$ ). The reaction rate constants ( $K_1$ ) for all the six photocatalysts were determined from the slope of the fitted curves (figure 7.10d) by means of linear regression and the values are given in table 7.1. All the plots show a linear relationship with good correlation coefficient ( $R^2 > 0.966$ ), indicating that the MG degradation by the prepared photocatalysts under natural solar light degradation follows the pseudo-first-order kinetic model below: Here, it is observed that the highest apparent reaction rate constants  $k_{app}$ ,  $0.0714 \text{ min}^{-1}$  was calculated for  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30) nanocomposite. Furthermore, the extent of mineralization is evaluated by measuring the total organic carbon (TOC). After solar light irradiation for 90 min, the percentage of mineralization was found to be 71 % by using  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30) nanocomposite photocatalyst (0.1 g) in 100 ml of  $20 \text{ mg L}^{-1}$  MG solution.

**Table 7.1** Percentage of degradation and pseudo-first-order kinetic parameters of MG

Photocatalyst	Degradation (%)	$K_1$ ( $\text{min}^{-1}$ )	$R^2$
$\alpha\text{-Fe}_2\text{O}_3$	81.86	0.0183	0.996
$\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4$ (Fe:Zn=90:10)	88.37	0.0231	0.989
$\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4$ (Fe:Zn=80:20)	94.37	0.0309	0.991
$\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$ (Fe:Zn=70:30)	99.77	0.0714	0.966
$\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$ (Fe:Zn=60:40)	98.29	0.0441	0.984
$\text{ZnFe}_2\text{O}_4/\text{ZnO}$ (Fe:Zn=50:50)	96.92	0.0373	0.993

The stability of catalysts is an important issue for their practical applications. To prove the stability and the reusability of  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30) nanocomposite photocatalyst, we have repeated it four times for degradation of the MG and the result is shown in figure 7.11. Here, we have calculated the percentage of degradation only after dark reaction. As can be seen, the repeatability of the entire process and the final result of

degradation of MG are very good, which further demonstrate the excellent efficiency of the photocatalyst.

**Figure 7.11** Repeating experiments for the photocatalytic degradation of MO using  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30) nanocomposite under solar light irradiation.

### 7.3.3. Mechanism on enhancement of photocatalytic activity

The photocatalytic activity is influenced by some crucial factors like surface area, optical absorption, phase structure and separation efficiency of photo-generated charge carriers (Aslam et al., 2015). From the experimental results, it is observed that the photocatalytic activities of  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4$ ,  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  and  $\text{ZnFe}_2\text{O}_4/\text{ZnO}$  nanocomposites are higher than that of pristine  $\alpha\text{-Fe}_2\text{O}_3$  nanoparticle. This can be attributed to the formation of the hetero-nanostructure. The evolution of phase/nanocomposites with addition of Zn salt precursor up to 30 % results with (a) increased surface area, (b) reduced band gap and (c) easily separation of generated electron-hole pair due to formation of hetero-nanostructures. But for  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30) nanocomposites, additional mechanism of cascade electron transfer is presumed due to the presence of ternary hybrid structure; which is not possible in binary hybrid/composite system. Similar type of evidences is also reported by Kim et al. (2011). The mechanism is schematically described in figure 7.12. When the  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30) ternary nanocomposite was irradiated by solar light, the energy of solar light exceeds band gap of  $\text{ZnFe}_2\text{O}_4$  (1.92 eV), the VB  $e^-$  of  $\text{ZnFe}_2\text{O}_4$  were excited to CB ( $E_{\text{CB}} = -1.54 \text{ V}_{\text{NHE}}$ ) creating  $h^+$  in the VB. Then the photogenerated  $e^-$  of  $\text{ZnFe}_2\text{O}_4$  was immediately transferred to CB of  $\text{ZnO}$  ( $E_{\text{CB}} = -0.31 \text{ V}_{\text{NHE}}$ ). Again the photogenerated  $e^-$  from  $\text{ZnO}$  were transferred to the CB of  $\alpha\text{-Fe}_2\text{O}_3$  ( $E_{\text{CB}} = +0.35 \text{ V}_{\text{NHE}}$ ). As a result, a high concentration of free electrons was formed in the conduction band of  $\alpha\text{-Fe}_2\text{O}_3$ . This makes the charge separation more effective and hence the electrons and holes migrate to the surface of respective particles and participate in the redox reaction. In the reaction

mechanism, the photogenerated electrons reduced the dissolved oxygen into peroxide ( $\text{O}_2^{\bullet-}$ ) or hydroxyl ( $\text{HO}^{\bullet}$ ) radicals; meanwhile the photogenerated holes likely to oxidize  $\text{H}_2\text{O}$  to form  $\text{HO}^{\bullet}$  radicals. The  $\text{HO}^{\bullet}$  radicals from both the process can effectively oxidize MG into minerals as end products (Ahmed et al., 2015; Lin et al., 2013; Dai et al., 2014). But in case of only  $\text{ZnFe}_2\text{O}_4$  or  $\alpha\text{-Fe}_2\text{O}_3$  single phase, the usual recombination of electron-hole pairs takes place and a few of  $\text{e}^-$  and  $\text{h}^+$  can participate in photocatalytic process.

For addition of 40 % Zn salt precursor, the percentage of ZnO phase in the  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=60:40) nanocomposite is increased with slightly increase in the net band gap of nanocomposite. This results in the decrease of photocatalytic activity compared to  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30) nanocomposite. Again for 50 % Zn salt precursor, the formation of binary  $\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=50:50) phase is observed. Therefore cascade electron transfer is not possible and electron-hole pair recombination becomes more predictable mechanism. Hence, the photocatalytic activity for degradation of MG dye was found to be highest for  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  (Fe:Zn=70:30) nanocomposites than the series of photocatalysts prepared by varying the mole % of Zn from 10-50 %.

**Figure 7.12** A proposed solar light photodegradation mechanism of  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  nanocomposite.

To examine photogenerated charge transfer pathways, photoluminescence (PL) emission spectra were obtained for the nanomaterials excited at wavelengths of 420 nm with 5/5 slit. The PL spectrum is related to the transfer behavior of the photoinduced electrons and holes so that it can reflect the separation and recombination of photoinduced charge carriers (Liu et

al., 2007; Khan et al., 2013). Figure 7.13 shows the PL spectra of pure  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub> (Fe:Zn=90:10), Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub> (Fe:Zn=80:20), Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=70:30), Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=60:40) and ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=50:50) nanoparticles. It can be seen that the PL intensity decreased dramatically when the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> was coupled with the ZnFe<sub>2</sub>O<sub>4</sub> to form Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub> nanocomposites. The reason behind the decrease in intensity is formation of heterojunctions between Fe<sub>2</sub>O<sub>3</sub> and ZnFe<sub>2</sub>O<sub>4</sub>. The potential difference between Fe<sub>2</sub>O<sub>3</sub> and ZnFe<sub>2</sub>O<sub>4</sub> allowed photoelectrons to easily migrate from the Fe<sub>2</sub>O<sub>3</sub> surfaces to the ZnFe<sub>2</sub>O<sub>4</sub> conduction band. This resulted in a decrease in the radiation combination of photoinduced electrons on the composite surfaces and hence weakening the PL intensity. In case of Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO, the decrease in PL intensity is more significant and lowest for Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=70:30). After that in case of ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=50:50) the PL intensity increases. This indicates that the ternary nanocomposites are more effective in inhibiting the charge recombination than binary nanocomposite. It is presumed that photogenerated electrons are effectively transported from ZnFe<sub>2</sub>O<sub>4</sub> to Fe<sub>2</sub>O<sub>3</sub> through ZnO. This is considerable evidence for the cascaded electron transfer.

**Figure 7.13** Photoluminescence emission spectra of a)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticle, b) Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub> (Fe:Zn=90:10), c) Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub> (Fe:Zn=80:20), d) Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=70:30), e) Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=60:40), f) ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=50:50) nanocomposites an excitation wavelength of 420 nm.

## 7.4. Conclusions

In summary, we have synthesized natural solar light sensitive photocatalysts of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles and Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>, Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO and ZnFe<sub>2</sub>O<sub>4</sub>/ZnO nanocomposites with various morphologies by a facile hydrothermal method. Morphology, crystalline phase, BET surface area and optical absorption of the nanostructures are strongly influenced by the molar ratio of Fe<sup>3+</sup> and Zn<sup>2+</sup>. XRD result gives the well crystalline nature of the prepared samples with appropriate phase without the presence of any impurity. From FE-SEM, we have observed irregular shape  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles having diameter in the range of 80-100 nm, which gradually becomes cubical shape in due formation of Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO & ZnFe<sub>2</sub>O<sub>4</sub>/ZnO mixed oxide nanocomposite with an increase in zinc content. The narrow band gap semiconducting nature of the samples was analyzed by UV-Vis-DRS technique. This prepared composite nanomaterials were used for photocatalytic degradation of Malachite green (MG) under natural solar light. It was observed that the nanocomposites show enhanced photocatalytic activity compared to pristine  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles. The Fe<sub>2</sub>O<sub>3</sub>/ZnFe<sub>2</sub>O<sub>4</sub>/ZnO (Fe:Zn=70:30) exhibits highest photocatalytic activity than other compositions. It is due to the effective cascaded electron transfer of photogenerated electrons from ZnFe<sub>2</sub>O<sub>4</sub> to Fe<sub>2</sub>O<sub>3</sub> through ZnO.

## CHAPTER-8

### SUMMARY AND CONCLUSIONS

In this research work, we have successfully synthesized different metal oxide nanomaterials especially iron oxides and iron oxide based mixed oxide composite nanomaterials such as  $\text{Fe}_2\text{O}_3\text{-SnO}_2$ ,  $\text{Fe}_2\text{O}_3\text{-CuO}$ ,  $\text{Fe}_2\text{O}_3/\text{ZnFe}_2\text{O}_4/\text{ZnO}$  and  $\text{MgFe}_2\text{O}_4/\text{Fe}_2\text{O}_3$  using precipitation, hydrothermal and reflux methods. We have also prepared iron oxide impregnated mesoporous MCM-41 by wet chemical impregnated method. The formation, phase, structure, size, shape, surface morphology, surface area and sorption studies of the synthesized iron based mixed oxide composite nanomaterials have been characterized by using different characterization techniques such as: XRD, SEM, FESEM, EDAX, TEM, XPS, FTIR, UV-VIS and BET analytical techniques. The obtained composite nanomaterials were used as adsorbents and photocatalysts for adsorptive removal and photocatalytic degradation of toxic organic dyes. Both cationic and anionic dyes having different functional groups such as Congo red (CR), Methylene blue (MB), Malachite green (MG) and Methyl orange (MO) have been selected as model organic pollutants in this study. The following major conclusions have been drawn from this study.

### MAJOR CONCLUSIONS

- Among the three Fe based nanorods ( $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ ,  $\gamma\text{-Fe}_2\text{O}_3$  and  $\alpha\text{-Fe}_2\text{O}_3$ ) synthesized by precipitation method, maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ) nanorods are demonstrated as very good adsorbent for removal of Congo red (CR) dye with maximum sorption capacity of 232 mg/g.
- The rod shaped  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  composite nanomaterials were synthesized by same precipitation method by varying the molar ratio of Fe and Sn salt precursors. The diameter of the nanocomposite were found to be in the range of 100-200 nm
- Presence of  $\text{SnO}_2$  in the  $\text{Fe}_2\text{O}_3$  matrix selectibly stablizes the  $\gamma\text{-Fe}_2\text{O}_3$  phase in the  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  nanocomposite. The  $\text{Fe}_2\text{O}_3\text{-SnO}_2$  (Fe: Sn = 8: 2) composite nanorod showed highest percentage adsorption with sorption capacity of 182 mg/g, which is better than that of  $\alpha\text{-Fe}_2\text{O}_3$  nanomaterials.
- The iron oxide impregnated mesoporous MCM-41 (Fe-MCM-41) prepared by a facile wet chemical method and is regarded as a very efficient adsorbent for removal of Methylene blue (MB) dye. It is observed that the impregnation of iron oxides into

MCM-41 matrix improve the sorption performances. The maximum sorption capacity of Fe-MCM-41 is found to be 194 mg/g.

- MgO nanostructures with different morphologies have been prepared by using above mentioned wet chemical methods. Among the various prepared MgO nanostructures, the hierarchical MgO nanomaterials prepared by reflux method exhibits excellent sorption capacities of 1205 and 1051 mg/g, for the adsorptive removal of Malachite green and Congo red dyes, respectively from aqueous syetem.
- An attempt has been made to prepare  $\text{Fe}_2\text{O}_3$ -MgO using the identical synthetic procrdure. Intrestingly, we have obtained  $\text{MgFe}_2\text{O}_4$ - $\text{Fe}_2\text{O}_3$  nanocomposites. The  $\text{MgFe}_2\text{O}_4$ - $\text{Fe}_2\text{O}_3$  nanocomposite prepared by precipitation method was found to be an efficient visible light photocatalyst for effective degradation of Methylene blue.
- We have also prepared  $\text{Fe}_2\text{O}_3$ -CuO nanocomposite by precipitation method, which exhibits enhanced photocatalytic activity than individual  $\text{Fe}_2\text{O}_3$  and CuO nanoparticles for degradation of Methyl orange from aqueous media under solar light irradiation.
- Furthermore, the  $\text{Fe}_2\text{O}_3$ -ZnO mixed oxide nanocomposites obtained by varying different molar ratio of Fe and Zn salt contents using hydrothermal method. Depending upon the composition,  $\text{Fe}_2\text{O}_3$ - $\text{ZnFe}_2\text{O}_4$ ,  $\text{Fe}_2\text{O}_3$ - $\text{ZnFe}_2\text{O}_4$ -ZnO and  $\text{ZnFe}_2\text{O}_4$ -ZnO mixed oxide nanocomposites were obtained in single step.
- Among all the nanocomposite materials, the ternary  $\text{Fe}_2\text{O}_3$ - $\text{ZnFe}_2\text{O}_4$ -ZnO (Fe:Zn=70:30) nanocomposite exhibits highest photocatalytic activity for catalytic degradation of Malachite green using solar light irradiation. The mechanism of degradation follows a cascade electron transfer from  $\text{ZnFe}_2\text{O}_4$  to ZnO to  $\text{Fe}_2\text{O}_3$  in the ternary hybrid nanostructure.

9. J. P. Dhal, B. G. Mishra and G. Hota, Rod shaped maghemite ( $\gamma$ - $\text{Fe}_2\text{O}_3$ ) nanomaterials for adsorption of Chromium (VI) and Fluoride ions from aqueous media (To be communicated).

### Conference Papers

1. J. P. Dhal, B. G. Mishra and G. Hota, Synthesis and characterization of novel metal oxide nanostructures for adsorption/catalytic degradation of organic pollutants from aqueous stream, Research Scholars Week, May 11-13, **2015**, NIT Rourkela.
2. J. P. Dhal, B. G. Mishra and G. Hota, Electrospun  $\alpha$ - $\text{Fe}_2\text{O}_3$  nanofiber for natural solar light driven photocatalytic degradation of Methylene Blue dye, ACBIR-2014, 10-11 January **2014**, NIT Rourkela.
3. J. P. Dhal, B. G. Mishra and G. Hota: Synthesis and characterization of iron oxide nanorods for decontamination of organic dye from aqueous media, CTSST 2014, 28 February **2014**, Sambalpur University, Odisha.
4. J. P. Dhal, B. G. Mishra and G. Hota, Synthesis, characterization and photocatalytic application of  $\alpha$ - $\text{Fe}_2\text{O}_3$  nanorod, ICMAT 2013, 30 June to 5 July **2013**, Suntec, Singapore.
5. J. P. Dhal, B. G. Mishra and G. Hota; Synthesis, characterization and photocatalytic application of ultra-fine  $\alpha$ - $\text{Fe}_2\text{O}_3$  nanofiber, International conference of Nano Science and Nanotechnology (ICONN 2013), at SRM University, Chennai, 18-20th March, **2013**.

## **CURRICULUM VITAE**

**Name:** Jyoti Prakash Dhal

**Date of Birth:** 28-06-1984

**Educational Qualifications:** M.Tech. (Metallurgical & Materials Engineering), National Institute of Technology, Rourkela, India (2011).

M. Sc. (Chemistry), Utkal University, Bhubaneswar, India (2006)

B. Sc. (Chemistry Honors), Utkal University, Bhubaneswar, India (2004)

Class XII, Christ College, Cuttack, CHSE-Odisha, India (2001)

Class X, Barunei High School, Jajpur, BSE-Odisha, India (1999)

**Research Experience:** 4 years research experience in the field of Material Science. Published 5 papers and communicated 4 papers in International journals.

**Professional Experience:** Three years of teaching experiences to Intermediate and U. G. students.

**Awards & Achievements:** Senior Research Fellow, MHRD, Govt. of India– July 2011 to till date.

Junior Research Fellow, MHRD, Govt. of India – July 2009 to June 2011.

Qualified GATE (2009) with 89.01 percentile.

Awarded BEST POSTER by NIT Rourkela on the occasion of Research Scholar Week 2015.

Rashtrapati Scout Certificate from Honourable President of India (1999).

**Permanent address:** S/O-Sudhakar Dhal  
At/Po-Bachhol, Via-Mashra,  
Dist- Jajpur, Odisha, India,
